The complications of diverticulitis (perforation abscess or chronic obstruction) are treated with sulfonamides and antibiotics and frequently require a temporary diverting colostomy followed later by resection of the involved colon and closure Primary segmental resection with an end to end anastomosis in one stage is reserved for patients with repeated attacks of diverticulitis who are operated on during the interval phase after the inflammatory reaction has subsided

CANCER OF THE COLON AND RECTUM

Cancer of the rectum and colon is responsible for approximately 16 per cent of all cancer deaths the region ranking second only to the stomach as the most common site of malignancy of the digestive tract It causes about 27 000 deaths in the United States yearly and occurs more commonly in men than in women—usually in the fifth sixth and sev

the reach of the proctosigmoidoscope Barium enema and air contrast studies are diagnostic in the vast majority of cases (over 90 per cent) although less accurate in the rectum and rectosigmoid areas than elsewhere Criteria for malignancy are (1) a persistent filling defect whose outline is irregular and stiff (2) strictures or persistent annular narrowing of the bowel (dilatation or distention of the colon above a tumor is common) (3) persistent obstruction to the flow of barium and (4) infiltration and ulceration with loss of normal mucosal pattern (Fig 185) The oral barium meal is strongly contraindicated in obstructing growths since it may produce acute intestinal obstruction

Differential Diagnosis The differential diagnosis of malignant tumors of the colon on the left side include (1) irritable colon (2) diverticulitis (3) chronic ulcerative colitis (4) fecal impaction (5) hemorrhoids (6) benign tumors and (7) lymphogranuloma venereum Lesions in the right half must be differentiated from (1) regional enteritis (2) appendical abscess (3) renal neoplasm (4) gastric cancer (5) peptic ulcer (6) gallbladder disease (7) blood dyscrasias with anemia (8) tuberculosis (9) amebic abscess and (10) carcinoid tumors

Complications The complications of carcinoma of the colon are often responsible for the presenting symptoms

Partial *obstruction* occurs in approximately 40 per cent of all colon cancers and in 75 to 80 per cent of left colon tumors particularly in the rectosigmoid The obstruction usually develops slowly but may be precipitated suddenly by *impaction* with feces or barium local edema *volvulus* or *intussusception* of the tumor

Ulceration particularly of the nodular and colloid type of adenocarcinoma produces gross or microscopic bleeding *Secondary infection* and *necrosis* may lead to *perforation peritonitis abscess* and *fistula* formation Pressure of the tumor upon the ureter results in *hydronephrosis*

Treatment The only effective treatment is surgical removal of the tumor by resection Combined abdominoperineal resection of the rectum with a permanent abdominal colostomy offers the best opportunity for cure of cancer of the rectum and may be performed as a one stage procedure In selected cases in which the tumor is located above the peritoneal reflection (10 to 15 cm from the anal canal) segmental resection may be performed without a colostomy and with preservation of the anal sphincter Palliative resection is indicated whenever possible despite distant metastases The resectability rate for cancer of the colon and rectum approximates 60 to 70 per cent and is higher in the right half of the colon than the left The surgical mortality ranges between 3 and 10 per cent

Prognosis Five year cures approximate 45 per cent for resectable cancers of the colon and rectum Only 26 per cent of all patients entering the hospital with cancer of the colon and rectum survive 5 years however Lymphatic metastases can be demonstrated in 53 per cent of all patients operated upon for colonic or rectal cancer Duke s classification of tumors establishes the prognosis upon the extent of tumor growth and the presence and extent of lymphatic metastases The 5 year survival rate (60 per cent) is considerably higher in selected patients in whom there is no lymphatic spread Carcinomas of the colon may remain localized for long periods before metastasizing The colloid carcinoma malignant melanomas epithelioma and lymphomatous sarcoma offer the poorest outlook The prognosis is less favorable in the younger age group and is better in women than in men

POLYPS OF THE RECTUM AND COLON

The adenomatous polyp is the most common benign tumor of the colon and rectum occurring in 7 to 9 per cent of the adult population—more often in men than in women and more frequently in the older age groups although it is seen at all ages The polyps may appear singly or as multiple sessile or pedunculated polypoid tumors

Benign mucosal *adenomatous polyps* are particularly significant since they often undergo malignant change and are found in 25 per cent of all resected cancers of the rectum and colon The distribution of adenomatous polyps in the rectum and colon closely parallels that of carcinoma A high percentage of malignant lesions of the colon and rectum originate in preexisting benign mucosal polyps and all stages between benign polyps and carcinoma can be demonstrated histologically Approximately 75 per cent of adenomatous polyps are in the rectum or sigmoid and the remainder are distributed in the middle and upper sigmoid (15 to 20 per cent) and ascending transverse and descending colon Multiple polyps are common (Fig 186)

The *papillary adenomas* constitute 15 per cent of all rectal polyps They are soft velvety villous projections with fine papillary folds involving a wide area of bowel and extending by epithelial proliferation They differ from adenomatous polyps in that they are tumors of the mucosal epithelium rather than of the mucosal glands and they invariably recur after fulguration These tumors are potentially highly malignant

Diffuse familial polyposis (polyposis intestinalis) involving the entire colon and rectum is found in

FIG 185 Annular carcinoma of the sigmoid at the junction of the sigmoid and descending colon Note the greatly narrowed lumen and the ragged napkin ring tumor encircling the colon Histologic examination revealed a poorly differentiated adenocarcinoma of the colon which completely infiltrated the wall

incomplete evacuation Gross bleeding is more common earlier in rectal cancer A decrease in the caliber of the stool occurs when the anus is involved or when anal spasm results from a lesion higher up

Carcinoma of the Right Half of the Colon Carcinoma of the right colon often produces nonspecific abdominal symptoms which are ill defined evanescent and often indistinguishable from those of the irritable bowel syndrome Constipation or diarrhea may occur but are less common than with carcinoma of the left colon Tumors in the hepatic flexure or transverse colon may produce cramping or colicky pain in the right lower quadrant simulating appendicitis Melena is rare *Anemia without* visible blood loss is common occurring in 25 to 50 per cent of patients and may be the cause of the presenting symptoms of weakness and fatigue A mass may be discovered in the right lower quadrant in 5 to 10 per cent of patients

Sarcomas and carcinomas are similar in their clinical pattern although sarcomas occur in younger persons present a more rapid clinical course with more pain and less tendency to hemorrhage and obstruction

Physical Examination There are usually no physical findings early in the disease Pallor resulting from anemia may be evident with lesions of the cecum and ascending colon before weight loss cachexia and other late signs of malignancy are apparent A tumor mass which is hard nodular nontender and fixed may be palpable abdominally

As already stated approximately 70 per cent of all rectal tumors are within reach of the index finger on rectal examination An extrarectal tumor mass in the sigmoid (or cecum) may be felt through the anterior wall of the rectum above the prostate in males (Blumer s shelf)

Audible or visible peristalsis abdominal distention and tympanites characterize obstructing lesions in the left half of the colon Hepatomegaly with or without ascites and lymphadenopathy signify metastases

*Laboratory Findings Anemia is present in two-*thirds of the patients with cancer of the cecum and ascending colon and is found in only one *third or less of patients with cancer of the left half* of the colon Macrocytic anemia observed with right side tumors in the absence of blood loss is unexplained and has been attributed both to an absorptive defect and to marrow suppression by the tumor itself Leukocytosis is absent unless secondary infection intervenes Occult blood is present in the stools of the majority of patients although negative stools do not exclude the diagnosis

Diagnosis The diagnosis of carcinoma of the colon is suggested by one or more of the following (1) vague dyspeptic symptoms weight loss and weakness (2) anemia without visible blood loss (3) a palpable mass by rectal or abdominal examination (4) alteration of bowel habit with alternating periods of diarrhea and constipation (5) *changes in the caliber of the stool (6) acute* subacute or chronic colonic obstruction (7) passage of blood bright or dark red with the stool Proctosigmoidoscopy barium enema and biopsy establish the diagnosis

Proctosigmoidoscopic Examination Approximately 70 per cent of all cancers of the colon and rectum can be visualized through the sigmoidoscope The direct visualization of a tumor particularly in the rectosigmoid where roentgen *diagnosis may be difficult is indispensable* The appearance of a polypoid nodular or ulcerated tumor is usually unmistakable Biopsy is helpful in establishing the diagnosis

Roentgen Examination Roentgen examination is indispensable for the diagnosis of tumors beyond

be considered premalignant lesions and removed whenever possible Adenomatous polyps of the rectum and sigmoid within the reach of the sigmoidoscope may be removed by excision and fulguration Polyps located beyond the reach of the sigmoidoscope are removed preferably by segmental resection of the involved colon particularly if the polyps are multiple Solitary polyps may be excised by polypectomy including a narrow elliptical portion of the wall of the bowel Adenomatous polyps demonstrating malignant change may require radical resection Papillary adenomas demand radical resection with or without preservation of the sphincter if the diagnosis is established by biopsy and inspection Repeated follow up sigmoidoscope and roentgen examinations at regular intervals are essential for all patients with rectal and colonic polyps because of the high incidence of recurrence and the later development of cancer Polyposis of the congenital type is treated by resection of the entire colon and rectum because of its highly malignant nature

OBSTRUCTION OF THE COLON AND RECTUM

Obstruction of the large bowel deserves special consideration because of inherent differences from small intestinal obstruction in respect to etiology symptomatology and treatment

Etiology *Chronic Obstruction* Primary *carcinoma* of the sigmoid flexure and rectum is the most common cause of chronic obstruction of the large bowel Next in frequency are *diverticulitis* and *inflammatory strictures* (ulcerative colitis lymphogranuloma venereum bacillary dysentery typhoid) Chronic obstruction may result from (1) fecal impaction (2) megacolon (3) endometriosis (4) large polyps (5) pelvic infections and tumors (6) traumatic strictures (mechanical or operative) (7) irradiation reaction following treatment of cancer of the cervix and (8) congenital anomalies (imperforate anus rectal malformations)

Acute Obstruction In contrast to the situation in the small intestine where adhesions and hernia are most often responsible for acute obstruction (77 per cent) primary *carcinoma* is the most common cause of *acute* obstruction of the large bowel Next in order of frequency are *volvulus diverticulitis* and *intussusception*

Volvulus signifies torsion or twisting of a segment of bowel on its mesenteric axis usually in a clockwise direction Defective fixation of the mesentery a long flexure or an unusually long mesenteric attachment may predispose to its occurrence The ileocecal area (in children) and the sigmoid (in adults) are the most frequent sites Circulatory disturbances occur early and result in venous engorgement edema infarction gangrene and perforation

Intussusception is the invagination or telescoping of one portion of the intestine (intussusceptum) into an adjacent distal segment and occurs most commonly in children usually males Contributing factors in adults are pedunculated tumors cancer Meckel s diverticulum and foreign bodies Intussusception is seen most frequently at the ileocecal junction Edema hemorrhage and induration of the intussusceptum may be followed by ulceration gangrene and perforation of the bowel

Reflex ileus (paralytic ileus) and *metabolic ileus* are discussed elsewhere (Chap 5)

Vascular Occlusion This form of obstruction is caused by interruption of the normal blood supply to the bowel as a result of embolism or thrombosis of the mesenteric vessels

Physiology and Pathology The pathologic physiology of acute *small intestinal obstruction* differs from that of acute colonic obstruction In the small intestine there is a progressively increasing collection of fluid and gas above the obstruction producing progressive distention resulting in edema ulceration inflammatory changes and ischemia of the bowel wall above the site of obstruction Large amounts of fluid electrolytes and plasma escape directly into the lumen of the intestinal tract causing dehydration hemoconcentration hypochloremia alkalosis or acidosis hypoproteinemia hypopotassemia and azotemia

Acute *obstruction of the colon* rarely produces this picture of severe chemical imbalance The obstruction in the large bowel may be of the closed loop type because of a competent ileocecal valve which permits gas and fluid to enter the colon from the ileum but prevents their return into the small intestine Consequently there is little or no distention of the small bowel The distention of the large intestine may be extreme because of the accumulation of a large amount of fluid and gas presenting an acute surgical emergency requiring colostomy or cecostomy Extensive inflammation edema ulceration focal necrosis perforation and peritonitis result if decompression is not performed promptly

Symptoms Colonic obstructions except for volvulus and intussusception are often insidious in onset and may present a history of previous mild attacks suggesting incomplete obstruction This is particularly true of carcinoma and diverticulitis An abrupt onset similar to that seen in small intestinal obstruction usually occurs with volvulus and intussusception The characteristic symptoms of chronic large bowel obstruction are (1) insidious progressive con

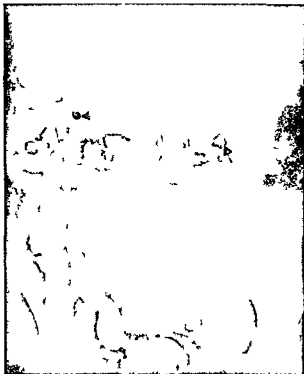

FIG 186 Polyps in the ascending and transverse colon in a 44 year old woman complaining of rectal bleeding

childhood adolescence or early adult life and is classified as the congenital type of polyposis inherited as a simple dominant mendelian trait (Fig 187) Malignant degeneration occurs invariably in this disease *Pseudopolyps* associated with inflammatory diseases such as ulcerative colitis are not true adenomas although they may predispose to cancer

Other less common benign tumors include fibromas *lipomas myomas angiomas adenomyomas* and enterogenous and gas cysts

Diagnosis More than 75 per cent of all benign polyps may be visualized and biopsied through the sigmoidoscope Radiographic studies by air contrast techniques are often necessary to demonstrate polyps and other tumors beyond the reach of the sigmoidoscope

Symptoms Benign tumors and adenomatous polyps may produce no symptoms Bleeding is the most common presenting complaint Less than one third of the patients experience rectal bleeding cramplike abdominal pain or diarrhea although persistent occult blood in the stools may be present more frequently Solitary pedunculated tumors may cause intermittent colicky pain colonic obstruction or intussusception Lipomas are prone to intussusception hemangiomas to bleeding

Treatment Surgical resection of benign tumors *such as fibromas and lipomas* is the procedure of choice All polyps of the rectum and colon should

FIG 187 (*Upper*) Diffuse polyposis of the familial type involving the entire colon and rectum of a 29 year-old male complaining of diarrhea tinged with bright red blood weakness and fatigue (*Lower*) Resected specimen of colon demonstrating extensive polyposis These were benign adenomatous polyps which extended from the ileocecal valve to within 1 cm of the anal orifice

patients with intestinal obstruction are the correction of fluid and electrolyte disturbances removal of the obstructive agent and restoration of normal bowel function This may be accomplished by (1) administration of fluids electrolytes blood and plasma, (2) decompression of the distended intestine by intubation, enterostomy or colostomy and (3) surgical correction and removal of the obstructing mechanism

Fluid electrolyte and vitamin replacement therapy and maintenance of caloric and nitrogen balance must be individualized for each patient, depending upon the level, type and duration of the obstruction and upon his clinical state The principles of such therapy in this condition are discussed in Chaps 48 and 49 Shocklike states accompanying vascular obstruction such as mesenteric thrombosis or embolism volvulus, intussusception and strangulation often require whole blood or plasma transfusions

Obstruction of the colon constitutes an acute surgical emergency in (1) acute closed loop obstruction (2) strangulating obstruction regardless of cause (3) intussusception and (4) volvulus Acute closed loop obstruction requires decompression cecostomy or colostomy Strangulation necessitates laparotomy with removal of the gangrenous segments of bowel The management of intussusception may vary In selected cases reduction by barium enema is successful, but it should be performed under surgical supervision with adequate preparation for prompt operative intervention Volvulus of the sigmoid uncomplicated by strangulation may be treated by sigmoidoscopic decompression with a soft rubber tube Carcinoma of the colon associated with complete obstruction requires preliminary decompression by cecostomy or colostomy Usually the obstruction is incomplete however and adequate decompression may be attained by the use of sulfonamides or antibiotics cleansing enemas, and a bland diet Obstructing cancer of the colon can be decompressed by intubation if the ileocecal valve is incompetent Decompression of the intestinal tract by intubation is often effective in the treatment of paralytic ileus

Drugs which stimulate peristaltic activity as well as the use of enemas have only a transient effect on paralytic ileus and are contraindicated in acute mechanical obstruction of the small intestine or colon

Antibiotics such as penicillin and streptomycin and the sulfonamides may be of value in the treatment of obstruction and are indicated particularly when surgical intervention is anticipated

The choice of the surgical procedure depends upon the cause of the obstruction, viability of the bowel and the clinical state of the patient

CONGENITAL ANOMALIES

Megacolon

Two types of congenital megacolon are encountered Hirschsprung's disease and idiopathic megacolon

Primary megacolon or Hirschsprung's disease is a congenital dilatation elongation and hyper trophy of the sigmoid colon involving at times the entire colon and accompanied by the retention of enormous amounts of feces (Fig 188)

Hirschsprung's disease is characterized by a functionally abnormal narrowed segment of bowel involving the rectosigmoid and rectum with a dilated and hypertrophied colon above (Fig 188) The cause of the narrowed segment has been attributed to the absence of ganglion cells in Auerbach's plexus resulting in an "obstructive" segment on a neurogenic basis

The symptoms appear at birth or during infancy and are more common in males Constipation is often so severe that weeks or months may elapse without a spontaneous evacuation Abdominal distension with gas may be pronounced and intermittent acute attacks of obstruction and vomiting are common Hyperactive peristalsis manifests itself by loud resounding borborygmi Rectal examination reveals an empty rectum and an impacted sigmoid colon Demonstration by roentgenogram of a narrowed rectum and rectosigmoid with marked dilatation of the sigmoid colon establishes the diagnosis (Fig 188)

Medical management is ineffectual in Hirschsprung's disease The most satisfactory surgical procedure consists of an abdominal resection of the narrowed aganglionic distal segment (rectum and rectosigmoid) with a "pull through" anastomosis preserving the anal sphincter

Idiopathic megacolon differs significantly from Hirschsprung's disease (1) It may not become evident symptomatically until 2 to 3 years or more after birth (2) Abdominal distention occurs less commonly constipation is less pronounced and vomiting is infrequent (3) Impactions are found within the rectum (4) A narrowed segment cannot be demonstrated roentgenologically and the entire rectum and rectosigmoid appear dilated

Treatment consists of a bland low residue diet, enemas mineral oil or other laxatives and cholinergic drugs

Other Anomalies of the Anus Rectum and Colon

Other congenital anomalies include redundant colon anomalies of rotation descent and fixation duplication and triplication of the colon atresia of the anal canal rectum or sigmoid imperforate anus and congenital strictures of the rectum

stipation (2) distention without vomiting and (3) colicky recurrent abdominal pain

Constipation is common in all forms of obstruction after the intestine distal to the occlusion has been emptied Obstipation and the inability to expel flatus often follow Paradoxical diarrhea may occur if liquid feces pass around an impaction or tumor in a dilated rectum

In contrast to the frequent and copious vomiting associated with high obstruction of the small intestine vomiting is frequently absent in colonic obstruction in spite of severe distention Marked distention without vomiting is particularly characteristic of closed loop obstruction described previously

In colonic obstruction intermittent colicky abdominal pain may be absent or is frequently atypical and should not be regarded as a presenting or essential sign This is in sharp contrast to small bowel obstruction in which severe intermittent colicky midabdominal pain characteristically occurs in paroxysms increases rapidly to a peak in crescendo fashion and remains sustained at its maximum intensity usually for 1 to 3 min before ceasing abruptly There is usually no pain between paroxysms except with strangulation when the pain becomes constant

With increasing distention the contractability of the colon is diminished and the colic decreases in severity Pain is frequently absent in functional ileus and tends to be rhythmic in intussusception

Blood in the stools in acute colonic obstruction suggests cancer diverticulitis, or strangulation Vascular occlusion is accompanied by acute abdominal pain tenderness and rigidity shock rapid pulse and respiration vomiting or diarrhea The passage of blood and mucus by rectum in children with periodic attacks of abdominal pain vomiting and a palpable tumor indicates intussusception Extreme fulminant distention developing in a very short time is characteristic of volvulus of the right or left colon

Physical Findings During the early postobstructive period the patient usually presents no significant change in appearance As the disease progresses a shocklike picture may develop if strangulation and impairment of blood supply intervene Dehydration and electrolyte imbalance are less likely to occur in colonic obstruction in contrast to small intestine obstruction

Abdominal examination reveals distention tympanites abnormal peristaltic activity and variable degrees of abdominal tenderness depending upon the cause of the obstruction In simple obstruction the abdominal wall may remain soft and nontender although some tightening of the abdominal muscles may be discernible during paroxysms of colic

In carcinoma a palpable abdominal tumor is an important diagnostic clue A sausage-shaped mass of an advancing intussusception is a significant diagnostic sign particularly in children

Interference with the blood supply accompanies volvulus or intussusception and may be caused by overdistention of the bowel from any cause Perforation and leakage are manifested by abdominal tenderness increased pulse rate rigidity or a mass Abdominal tenderness may be present directly over a distended twisted loop of bowel in volvulus or over an obstructing carcinoma or area of diverticulitis

Auscultatory findings are often significant Characteristically borborygmi may be heard at the height of the attacks of pain Its concomitant occurrence with each paroxysm indicates intestinal colic The loud gurgling bubbling noises may assume a metallic tinkling character as the obstruction progresses In adynamic ileus and the late stages of obstruction the abdomen becomes silent

The presence of a mass or stricture on rectal examination may reveal the source of the obstruction

Diagnosis. The laboratory studies in large-bowel obstruction may reveal anemia or hypoproteinemia on the basis of blood loss or malnutrition in contrast to the dehydration and hemoconcentration commonly seen in small intestine obstruction In the early phase of colonic obstruction the laboratory studies are essentially normal except perhaps for persistent occult blood in the stools

Roentgen examination is one of the most valuable procedures in diagnosis "Scout" films of the abdomen taken with the patient in the erect and supine positions will aid in localizing the site of obstruction by the distribution of gas and fluid levels in the small intestine or colon Roentgenograms taken with the patient in an upright position may reveal numerous fluid levels in dilated loops of bowel one above the other in a step-ladder pattern indicating small intestinal obstruction Distention limited entirely to the colon is evidence of complete competency of the ileocecal valve and often presents a classic roentgen picture The characteristic roentgen picture of volvulus is that of extreme distention restricted to a closed loop of colon In sigmoid volvulus the distended colon appears on the right side and in cecal volvulus on the left

A barium enema may be helpful in determining the site of occlusion Barium by mouth is contraindicated in cases of suspected intestinal obstruction Proctosigmoidoscopy with biopsy may often establish the diagnosis particularly in chronic obstruction caused by carcinoma

Treatment The objectives in management of

or cotton after defecation witch hazel packs bland *ointments or calamine* lotion may be helpful Subcutaneous injection of the area with alcohol x ray therapy and hydrocortisone ointment have also been recommended

STRICTURES AND FISTULAS

The most common causes of strictures are cancer ulcerative colitis diverticulitis lymphogranuloma venereum operative procedures and radiation therapy Other inflammatory and granulomatous processes which may result in stricture formation are typhoid fever bacillary dysentery regional enteritis tuberculosis and syphilis

Fistulas may arise as a complication of surgery or a number of diseases including ulcerative colitis diverticulitis regional enteritis tuberculosis lymphogranuloma venereum and actinomycosis

LYMPHOGRANULOMA VENEREUM

This subject is discussed in Chap 188

COMPLICATIONS OF ANTIBIOTIC THERAPY

The administration of broad spectrum antibiotics (Aureomycin Terramycin, and chloramphenicol) may produce gastrointestinal disorders such as stomatitis monilial infections blacktongue proctitis epigastric or abdominal pain nausea vomiting diarrhea rectal bleeding intestinal deficiency patterns and pruritus ani presumably as a result of drug toxicity or alteration of the bacterial flora These complications are usually self limited and subside soon after the antibiotic is discontinued

Pseudomembranous Enterocolitis

This fulminant frequently fatal disease may be seen as a complication of antibiotic therapy alone or may occur after a wide variety of surgical procedures unrelated to the preoperative administration of broad spectrum antibiotics The syndrome appears to be related to an altered intestinal bacterial flora and an overgrowth of *Micrococcus pyogenes* organisms (*Staphylococcus aureus*) which are often found in the stools and intestinal lesions in pure culture

Symptoms The onset is usually abrupt and the clinical course rapid and progressive often leading to death in a few hours or days The disease is characterized by diarrhea fever cramping abdominal pain and distention nausea vomiting and profound circulatory collapse Severe diarrhea with passage of membranous shreds blood and pus is usually but not invariably observed Shock mental confusion or delirium dehydration oliguria and fluid and electrolyte imbalance are common

Pathology The mucosal surface of the bowel is covered by a yellow green or grayish brown friable pseudomembrane which may be observed anywhere from the esophagus to the rectum The small intestine and colon are most frequently involved The mucosa becomes necrotic peels off and forms a diphtheritic membrane containing cellular debris and bacteria Characteristically there is extensive denudation of the mucosa of the bowel and the colon contains tremendous quantities of fluid and gas Peritonitis is common

Etiology The cause of the disease is unknown The two dominant factors appear to be infection and tissue necrosis The choleralike state and the diffuse necrosis of the gastrointestinal mucosa have been attributed to the growth of resistant strains of *Micrococcus pyogenes* which elaborate exotoxins and endotoxins These organisms grow rampant on necrotic tissue particularly when other bacteria have been eliminated by antibiotic therapy Shock arteriolar vasospasm and intravascular clotting in the mucosal capillaries of the intestine are contributing factors in the tissue necrosis The syndrome has been observed following the use of any broad spectrum antibiotic but it existed postoperatively before the antibiotic era

Diagnosis The disease should be suspected in any instance of severe diarrhea particularly if fever toxicity and signs of circulatory collapse develop postoperatively or during antibiotic therapy Sigmoidoscopy may reveal an edematous friable necrotic mucosa resembling that of nonspecific ulcerative colitis *M pyogenes* organisms are usually demonstrable in stool cultures The syndrome may simulate peritonitis intestinal obstruction ulcerative colitis amebic or bacillary dysentery coronary thrombosis or pulmonary embolism

Treatment Treatment must be prompt and energetic Erythromycin (500 mg or more four times daily depending upon bacterial sensitivity) should be administered promptly and all other antibiotics discontinued In some instances the newer antibiotic Novobiocin (500 mg every 8 hr) may be more effective Vigorous replacement of fluids and electrolytes is essential Blood transfusions may be helpful in combating shock The administration of 20 mg corticotropin intramuscularly three times daily for 4 to 10 days has been recommended

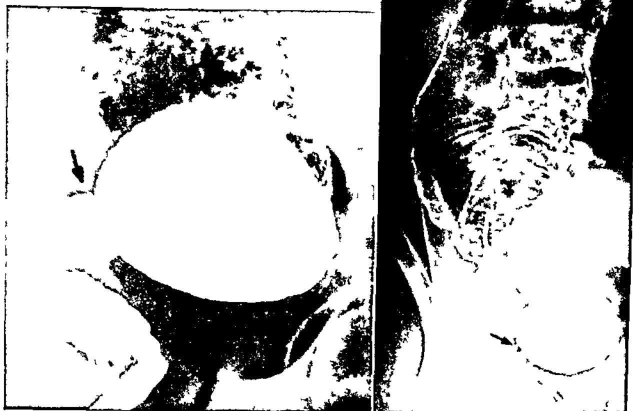

FIG 188 *Congenital megacolon (Hirschsprung's disease)* Note the contraction ring at the junction of the rectum and sigmoid with tremendous dilatation of the sigmoid colon above

HEMORRHOIDS

Hemorrhoids are superficial varices which appear at the anorectal junction Internal hemorrhoids arise above the anorectal junction and are covered with mucous membrane External hemorrhoids arise below the pectinate line and are covered with skin The most common contributing factors are constipation straining at stool chronic diarrhea heavy lifting or overexertion pregnancy tumors portal obstruction or any cause of increased intraabdominal pressure The sudden onset of pain and the presence of a firm tender localized swelling at the anal region indicate thrombosis Hemorrhoidal bleeding of bright red blood usually streaking the outside of the stool may produce chronic blood loss and anemia The diagnosis is made by history digital examination and direct examination through the anoscope

Treatment consists of correction of the constipation and diarrhea avoidance of straining at stool the use of mineral oil or rectal suppositories application of wet packs after defecation bland ointments and sitz baths In selected cases hemorrhoids which bleed and do not prolapse may be treated by injections of sclerosing solutions A thrombus may be removed by simple incision Excision of internal and external hemorrhoids is usually performed to alleviate pain and bleeding or because of prolapse perianal seepage infection and pruritus Surgery should never be performed without a previous proctosigmoidoscopy to exclude rectal cancer polyps or ulcerative colitis Hemorrhoidectomy is contraindicated in the presence of acute inflammation and ulcerative colitis

PRURITUS ANI

Intractable itching of the perianal area usually worse at night has been attributed to emotional difficulties hemorrhoids cryptitis proctitis fungous infections worms chemical irritants endocrine disorders allergic factors and antibiotics The exact mechanism is unknown There is no specific treatment Careful cleansing of the area with soft tissue

tension gastric varices and congestive splenomegaly Thrombosis or erosion of the splenic vein is an occasional complication of pancreatitis

Pancreatic Function Tests Pancreatic function tests depend on demonstrating either excessive amounts of pancreatic secretory products in the blood or insufficient amounts in the digestive tract Normal serum amylase concentration is less than 150 Somogyi units per 100 ml and lipase less than 1.5 Cherry Crandall units per 1 0 ml Trypsin inhibitors interfere with the direct determination of this enzyme in the blood but indirect evidence of proteolytic action may be detectable in that prothrombin and antitrypsin titers are depressed and fibrinolytic and antithrombic activities increased if pancreatic proteases accumulate in the blood Various "provocative" tests have also been advocated blood levels of amylase are measured before and after giving (1) morphine to increase sphincter of Oddi resistance and (2) secretin or a cholinergic agent to stimulate pancreatic secretion Because varied combinations of effects are possible these procedures are not reliable

Urinary concentrations of diastase reflect serum amylase changes but are more erratic The role of urinary lipase determinations is unsettled

Direct measurement of pancreatic secretion is accomplished by quantitative collection of duodenal contents after stimulation with secretin to increase volume and bicarbonate output or after cholinergic stimulation of enzyme output Following secretin stimulation the normal pancreas puts out a minimum of 2 ml per kg of juice per 80 min and a concentration of 90 mEq of $NaHCO_3$ per liter Rough tests for the presence of pancreatic ferments in the feces (i e gelatin film test) are not useful in adult patients

Indirect evidence of pancreatic exocrine function is obtained by various tests of absorption In general all tests in which a substance is administered by mouth and blood levels are subsequently measured are unsatisfactory because blood levels are affected by so many functions Examination of the feces for excessive loss of fat or protein is more reliable but abnormalities indicate impaired absorption not necessarily impaired pancreatic digestion Long term balance studies are probably most accurate satisfactory results can be obtained by the simpler method of measuring the fecal loss of I^{131} labeled fat or protein and microscopic examination of the stool for meat fibers and fat droplets (proper preparation of the specimen with 30 per cent acetic acid heat and sudanophilic stain is essential) is a rough test suitable for preliminary study and detection of advanced pancreatic insufficiency

Although abnormal glucose metabolism is a frequent manifestation of pancreatic disease evidence of such an abnormality is obviously not specific for infections or tumors of the pancreas

ACUTE PANCREATITIS

Acute pancreatitis is divided into the edematous hemorrhagic and necrotic varieties according to the pathologic change that predominates Although the clinical and pathologic features of the three types vary their pathogenesis is presumably the same and such differences as exist are attributable to the degree of pancreatic damage

Etiology Acute pancreatitis tends to occur in patients with alcoholism gallstones and peptic ulcer occasionally it appears as a complication of pregnancy essential hyperlipemia and diffuse vascular disease such as periarteritis nodosa A not infrequent cause is trauma either indirect as from a heavy abdominal blow or direct as from surgery in the upper abdomen Pancreatitis also appears in normal persons following a heavy meal and sometimes has no recognizable antecedent

The pathogenesis of pancreatitis presumably depends on intrapancreatic activation of proteolytic enzymes with consequent digestion of pancreatic tissue and blood vessels Such pancreatic autodigestion apparently may develop under two general conditions (1) when pancreatic secretion is obstructed either by a solitary lesion of a major duct or by diffuse blockage of many tiny ductules or (2) when acinar tissue is exposed to direct injury by toxins ischemia inflammation or trauma. Experimentally for example pancreatitis can be initiated by the combined procedure of obstructing the pancreatic ducts and injecting agents such as bile or bacteria to activate proteolysis This fact lends credence to the hypothesis that pancreatitis may develop if a stone in the ampulla of Vater or a spasm of the sphincter of Oddi impedes pancreatic secretion with reflux of bile into the pancreatic ducts Arguments against this theory are as follows reflux of bile into the pancreatic ducts may occur without untoward effects the secretory pressure of the pancreas equals or exceeds that of the biliary system and a common channel of pancreatic and common ducts long enough to permit reflux probably exists in less than 50 per cent of people

Direct injury to acinar tissue would appear to be responsible for the pancreatitis that follows pancreatic trauma or a penetrating peptic ulcer In animals the tissue damage and ischemia produced by a local Shwartzman reaction or by injection of staphylococcal toxin into the pancreatic ducts induces a fulminating pancreatitis The nature of alcoholic pancreatitis is obscure alcohol does not appear to have a direct effect on pancreatic function It has however been suggested that chronic pancreatitis in alcoholics may be a deficiency dis

249 DISEASES OF THE PANCREAS

Franz J Ingelfinger

Symptomatology The outstanding symptom of pancreatic disease is pain In addition pancreatic disorders may produce symptoms by altering the structure and function of any of the following systems (1) the pancreatic acini and ducts (2) the islands of Langerhans (3) the biliary passages (4) the gastrointestinal tract and (5) the portal circulation

Pain The pain of pancreatic disease roughly corresponds in location to the position of the lesion but its character is capricious and its borders are indeterminate Presumably made up of both true visceral and referred somatic components pancreatic pain is felt between the xiphoid and umbilicus in front and between the tenth thoracic and second lumbar vertebrae in back Frequently it bores through the body from front to back or vice versa but superficial radiation along the costal margin is unusual Because of the central position of the pancreas and its bilateral sensory innervation pain from a lesion confined to the head or tail tends to be felt centrally but with increased emphasis to right or left depending on the position of the lesion

Abnormalities of External Secretion The pancreatic juice amounting approximately to 1 500 ml per day contains water bicarbonate (60 to 120 mEq per liter) sodium (140 mEq per liter) potassium (4 mEq per liter) smaller quantities of other ions and numerous digestive ferments classified under the broad headings of trypsin amylase (diastase is used as an equivalent term) and lipase Loss of this entire secretion through an external pancreatic fistula leads to dehydration and electrolyte depletion In addition deviation of the pancreatic enzymes from the gut causes a fecal loss of about half the fat and 30 per cent of the protein ingested Carbohydrate is also digested poorly but hydrolysis by intestinal bacteria prevents its loss in the feces Similar absorptive defects follow total pancreatectomy complete obstruction of the ducts or extensive destruction of the gland by disease On the other hand subtotal resection of the pancreas or incomplete involvement by disease usually does not bring about obvious steatorrhea (fecal fat loss) or creatorrhea (fecal protein loss) since the reserve capacity of the surviving pancreatic acini is tremendous In dogs digestion may be unimpaired after resection of four fifths of the pancreas

Abnormalities of Internal Secretion The islands of Langerhans often remain relatively unaffected by inflammatory or neoplastic lesions of acinar tissue Consequently diabetes is often mild or even absent in the face of extensive pancreatic disease Total pancreatectomy in man is compatible with life provided that insulin requirements (about 50 units per day) are met and digestion is aided by oral administration of pancreatic material The suggestion that the islet cells elaborate a lipotropic hormone (lipocaic) has not been accepted Inadequate digestion and absorption of nitrogenous substances probably account for the fatty liver that attends total pancreatectomy in dogs

Disorders of the Biliary Passages Lesions in the head of the pancreas may obstruct the common bile duct producing jaundice Without a complicating infection such purely mechanical obstruction of 3 weeks duration or less rarely affects the liver seriously especially if a normal gallbladder is present (see Chap 251) It is possible but not established that reflux of normal or infected pancreatic juice into the biliary system may initiate disease in this organ

Gastrointestinal Disorders Nausea vomiting belching bloating distention or diarrhea are caused partly by the malabsorption of pancreatic insufficiency and partly by direct irritation or reflex stimulation of gastrointestinal motor function Digestive disorders also arise if the alimentary organs are displaced or compressed by pancreatic tumor and direct invasion of the stomach duodenum or transverse colon by cancer of the pancreas may lead to mechanical obstruction or bleeding

Disorders of the Portal Venous System Because of the intimate anatomic relationship of the splenic and portal veins and the pancreas hematogenous metastases to the liver are an early possibility in pancreatic cancer and neoplastic obstruction of the portal venous system may produce portal hyper

Table 127 DIFFERENTIAL DIAGNOSIS OF ACUTE PANCREATITIS

Disease	History	Physical examination	Laboratory findings
Acute pancreatitis	Sudden onset often with immediate maximal development of pain Past or recent history of gallstones alcoholism peptic ulcer dietary debauch trauma or upper abdominal surgery	Abdominal findings moderate as compared to violence of pain Tenderness extends to left of epigastrium Abdominal distention moderate or absent Peristaltic noises diminished or absent Shock and cyanosis may be striking Patient may be restless	Elevation of amylase in serum and urine Hypocalcemia in severe cases Paracentesis evidence of fat necrosis sometimes sanguineous fluid high amylase levels
Perforated viscus especially peptic ulcer	History of ulcer	Boardlike pain and tenderness in epigastrium Patient fears movement and jarring Shock rare	X ray shows free intraperitoneal air
Mesenteric vascular occlusion	Elderly patient with cardiovascular disease or recent operation Development of pain may be gradual		WBC over 20 000 Paracentesis sanguineous fluid
Acute intestinal obstruction	Intermittent colics with relative comfort between pain Past history of abdominal operation or of inguinal or femoral hernia	Abdominal distention with loud peristalsis Shock rare Patient moves around with colic	X ray of abdomen shows characteristics of mechanical obstruction
Biliary colic	Pain more right-sided more gradual in onset and less prostrating than that of pancreatitis	Tenderness maximal on right side of abdomen	
Coronary occlusion	Pain usually maximal in chest neck or arms	Relatively few abdominal findings Shock and restlessness often present	Electrocardiographic abnormalities
Dissecting aneurysm of aorta		Impaired femoral pulsations Shock and restlessness often present	Hematuria

The points listed are of presumptive importance as guides toward the correct diagnosis but they are not invariable features of the diseases under which they are grouped

retroperitoneal sepsis rupture into a major blood vessel with internal hemorrhage and persistent external pancreatic fistula following drainage procedures The disease may run a slow downhill course characterized by malnutrition ileus and diarrhea

Differential Diagnosis Any severe pain in the middle of the body should suggest pancreatitis A history of previous attacks of pain is common but also characterizes important differential diagnoses Once pancreatitis is suspected its diagnosis can usually be established by measurement of pancreatic enzymes in the blood by exclusion of the conditions most likely to simulate pancreatitis and by the course of the disease In considering the differential diagnoses (Table 127) it is well to remember that coronary occlusion and biliary colic are approximately twenty times as common as acute pancreatitis that perforated ulcer is three times as common that mesenteric vascular occlusion is except in postoperative cases somewhat less common and that a dissecting aneurysm is rarely seen

Elevation of serum amylase levels as occurs in pancreatitis sometimes is seen in mumps in patients given morphine (presumed reason contraction of

ease because chronic pancreatic changes characterize the deficiency disease kwashiorkor and because degenerative lesions can be induced in the pancreas of rats exposed to the methionine antagonist ethionine

Incidence Acute pancreatitis occurs rarely in children but affects adults of any age As might be anticipated from the incidence of the antecedent disorders pancreatitis associated with alcoholism duodenal ulcer or trauma is vastly more common in men than in women but even pancreatitis associated with gallstones is as common in the male as the female in spite of woman s greater tendency to form gallstones

Symptoms Severe upper abdominal pain usually beginning with catastrophic suddenness is the outstanding symptom Its degree varies with the violence of the pancreatic insult but it is rarely less than agonizing In mild (edematous) pancreatitis the patient may content himself with demanding analgesic medication in the hemorrhagic form he is anxious and restless even though motion may aggravate his suffering whereas the pain of necrotic pancreatitis is so severe as to produce shock Though centered initially in the upper midabdomen the violent pain of acute pancreatitis usually diffuses to the back chest and the lower abdomen

Nausea and vomiting abdominal bloating and constipation are frequent complaints Mild jaundice may be detected clinically or biochemically within 1 to 3 days of the onset in 25 per cent of cases In those with alcoholism psychotic episodes may complicate the picture

Physical Examination The patient is obviously distressed and anxious In some patients beads of sweat emphasize an underlying pallor in others subject to severe shock the face is livid and the extremities clammy Fever is usually not present initially and the pulse subject to a variety of defense mechanisms may be slow or fast strong or imperceptible The blood pressure reflects the degree of shock Tenderness voluntary resistance and spasm in the upper abdomen are present to a variable degree but these signs in striking contrast to the intense pain may be remarkably unimpressive Moderate abdominal distension and suppression of peristaltic sounds are frequent findings

Laboratory Data Urinary output is depressed in shock One out of four cases has glycosuria and the incidence of choluria is the same The white count ranges from 8 000 to 20 000 with increased polymorphonuclear cells A striking finding in severe cases is hemoconcentration with hematocrit values at times exceeding 60 per cent Mild hyperglycemia is common not only because of islet cell damage but also because of the patient s reaction to violent stress

The concentration of pancreatic enzymes in the blood provides the most specific laboratory information Within 8 hr of the onset of acute pancreatitis serum amylase values rise in 80 per cent of the cases to values exceeding 250 Somogyi units After 48 hr even in the face of clinical evidence of continuing pancreatitis amylase values tend to return to normal As amylase decreases blood lipase values rise in about half the patients to exceed 2 0 Cherry Crandall units and then subside slowly over a period of days to weeks In severe cases blood calcium levels fall from 3 to 10 days after the onset presumably because calcium soaps form with the fatty acids liberated by lipolytic destruction of abdominal and retroperitoneal fat

X ray Abdominal films may reveal moderately distended gas filled loops of intestine the paralytic ileus particularly affects the jejunal coils near the pancreas

Course Hemorrhagic or necrotic pancreatitis is fatal in over 50 per cent of the cases Almost all cases with edematous pancreatitis recover In the most severe cases death occurs within hours The mildest forms on the contrary subside completely with equal rapidity Most clinically recognized attacks run a course between these extremes Abdominal pain and distention persist or may reappear in bouts of renewed intensity expressing not only further pancreatic injury but also chemical peritonitis which develops as peripancreatic mesenteric and omental tissues are digested Concurrent with fat necrosis a dark bloody and cloudy peritoneal exudate accumulates in amounts ranging from 500 to 2 000 ml The patient at this point is no longer in shock but appears toxic and febrile Hypocalcemic tetany occurs in some cases

Hemorrhagic phenomena manifest at the onset of pancreatitis and reflecting proteolytic injury to clotting mechanisms are seen but rarely Three to six days later however edema and the typical blue green brown discoloration of a hematoma may appear on the abdominal wall either about the umbilicus or in the flanks (Grey Turner sign) The source of the blood is the hemorrhagic pancreas whence blood seeps by retroperitoneal routes to reach the abdominal wall

Late complications of pancreatitis are the formation of abscesses or pseudocysts (see Pseudocysts) an increased susceptibility to further attacks of pancreatitis and chronic pancreatitis The abscesses usually sterile are essentially collections of pancreatic secretions necrotic debris inflammatory cells and tissue fluids Pain fever chills and left sided pleural effusions are often evident The process may subside spontaneously or may drain by rupturing into the alimentary tract but surgical drainage is usually required Serious and life threatening complications are secondary bacterial infections at times by gas forming anaerobes perforation with

are readily palpable Their cystic nature however is difficult to ascertain for the mass as palpated through muscles tensed by considerable guarding may give the impression of hardness Signs of fluid or atelectasis at the left lung base are common X rays establish the location of the tumor and exclude lesions of the gastrointestinal tract and kidneys Jaundice occurs in 10 per cent of the cases

The principal differential diagnosis is upper abdominal neoplasm particularly of the pancreas If an attack consistent with pancreatitis has occurred within months the history is helpful but in approximately one out of three pseudocysts the initiating pancreatitis is mild atypical and unrecognized In these instances the existence of conditions predisposing to pancreatitis such as gallstones alcoholism duodenal ulcer or trauma provides a basis for suspecting a pseudocyst On the whole the patient with pseudocyst though perhaps febrile and distressed is not so debilitated as one would expect were his huge abdominal mass composed of neoplastic cells

In case of doubt exploratory surgery is always warranted Surgical treatment of a pancreatic pseudocyst consists of external or internal drainage or of removal with or without simultaneous resection of pancreatic tissue

Fig 190 Chronic relapsing pancreatitis In this film of the upper abdomen the entire pancreas is shown outlined by extensive calcific deposits

CHRONIC RELAPSING AND CALCAREOUS PANCREATITIS

Chronic relapsing pancreatitis sometimes is initiated by a clear cut attack of acute pancreatitis at other times it begins insidiously with atypical and relatively mild pains Whatever the onset the pancreas undergoes chronic changes consisting of acinar destruction inflammatory reaction interstitial fibrosis and variable damage to the islet cells In about half the cases calcific deposits form in the tubules the pancreatic substance or both (Fig 190) The name *calcareous* or *calcific* pancreatitis is often applied when the pancreas is irregularly calcified but the clinical characteristics are similar to those of chronic relapsing pancreatitis without calcific deposits The formation of pseudocysts is a common complication

As is true of acute pancreatitis the chronic varieties tend to appear in alcoholic patients those with gallstones or peptic ulcer and in those who have had upper abdominal trauma In the past gallstones have been considered as the principal antecedent but at present particularly in males with calcareous pancreatitis chronic alcoholism is the commonest background condition

Although chronic pancreatitis occasionally runs a painless course the outstanding symptoms are recurrent bouts of pain interspersed by periods either asymptomatic or characterized by persistent distress The episodic pains probably caused by limited but acute pancreatic inflammation resemble the pains of acute edematous pancreatitis in their character location and radiation The nature of the chronic distress is unpredictable partly because the patient with relapsing pancreatitis sometimes in alcoholic and sometimes addicted to narcotics after months of agonizing pain is a poor describer of his pains

The changes of chronic pancreatitis are so diffuse that some degree of pancreatic insufficiency is often manifest Because of impaired lipolytic and proteolytic activity digestion is impaired weight loss is striking and fatty and nitrogenous foods are lost in the stools The patient may consider his bowel movements normal but direct questioning reveals that they are bulky light and greasy in appearance and tend to float all indications of steatorrhea Although the absorption of vitamins D and K is impaired tetany and purpura such as occur in sprue are extremely unusual Frank diabetes occurs in only 10 to 15 per cent of the cases but impaired glucose tolerance is found in 75 per cent A few patients for unknown reasons manifest hyper

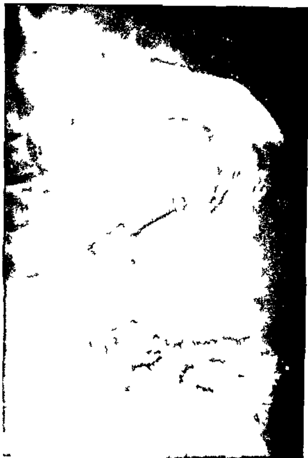

FIG 189 Pancreatic pseudocyst In this lateral view the body of the stomach appears to be pushed forward by a large mass between it and the spine The cause of the pseudocyst is well shown a large penetrating duodenal ulcer

sphincter of Oddi with temporary backing up of pancreatic juice) in perforated ulcer (presumed reason leakage of pancreatic enzymes from duodenal lumen into peritoneal cavity and thence absorption into blood) and in isolated instances of various other conditions particularly mesenteric vascular occlusion

Treatment Direct surgical attack with incision and drainage of the inflamed pancreas has been generally abandoned as ineffective and as incurring the risk of external pancreatic fistula Surgeons who believe that pancreatitis is caused by biliary reflux favor drainage of the common bile duct or the gall bladder in the hope of achieving decompression but the preponderant tendency at present is to treat pancreatitis conservatively

The rationale of therapy is (1) to keep pancreatic secretory activity at a minimum (2) to avoid any increase in ductile obstruction and (3) to prevent potential and treat actual complications Shock and hemoconcentration are treated with parenteral water electrolytes and human albumin Since opiates increase the resistance of the sphincter of Oddi meperidine is recommended on theoretical grounds for relief of pain but proves inadequate in many severe cases In such cases morphine or its derivatives may have to be used Nothing is given by mouth and constant gastric suction is used for several days to reduce intestinal distention and secretin production by the duodenum Fluid salt and small quantities of glucose are given intravenously with temporary disregard of caloric requirements Because secondary infection of necrotic tissue of partially obstructed biliary passages or of atelectatic lung is a dangerous possibility prophylactic daily doses of parenteral penicillin (1 000 000 or more units) and streptomycin (1 Gm) are advisable

Other less routine measures may be used Anticholinergics such as methantheline bromide (Banthine) 25 to 50 mg intravenously or 50 to 100 mg intramuscularly every 6 hr should inhibit the vagal phase of pancreatic secretion but these agents are usually effective only in the milder cases and in them parenteral anticholinergics are indicated Although experimental evidence suggests that inhibition of carbonic anhydrase with acetazoleamide (Diamox) decreases secretin stimulated pancreatic secretion the efficacy of Diamox in the management of pancreatitis has yet to be evaluated Paravertebral splanchnic or epidural procaine block sometimes relieves pain dramatically and some investigators believe that these procedures not only are symptomatic but also actually help the injured pancreas by augmenting its blood supply Hyperglycemia may require control with insulin Hypocalcemia is treated by injections of calcium gluconate 10 ml of a 10 per cent solution (90 mg of Ca) being given slowly by vein The total amount needed is determined by the patient s clinical response and his serum calcium level

As the patient improves foods may be given slowly beginning with a low fat low caloric intake which is increased according to individual tolerance Residual intraperitoneal abscesses may have to be drained eventually

PSEUDOCYSTS

Sometimes the collections of fluid and cellular debris that may follow pancreatitis produce only moderate inflammatory reaction but persist in chronic form for weeks to months Usually situated in the middle or left upper abdomen these pseudocysts may fluctuate in size or may form tremendous masses which create symptoms by pushing the duodenum to the right the stomach forward (Fig 189) the left diaphragm and lung upward and the transverse colon downward Aching distress rather than acute pain is the usual complaint

Pancreatic pseudocysts are tender and usually

creatic cancer jaundice occurs less frequently than weight loss or pain but diagnostically it is the most important symptom *It points specifically to the biliary passages* and *in lesions near the ampulla* of Vater gives early warning before extensive growth or metastasis has taken place The course and intensity of the jaundice depend on the degree of biliary obstruction (Table 128) In advanced cases *of cancer of the head of the pancreas it assumes* a deep greenish brown hue Itching is an associated symptom in three fourths of the cases

Laterally painless jaundice characterizes cancer in the head of the pancreas in only a few cases *More frequently the patient suffers from vague* abdominal distress and fullness sometimes worse sometimes better after eating The severe pain of cancer in the body or tail may however be diagnostic it bores through to the midback when the patient lies supine and he obtains relief only by standing or by sitting hunched up with arms clasped about the knees

Physical Examination Physical examination may reveal nothing except jaundice and the excoriations produced by scratching *In spite of biliary obstruction hepatic enlargement is not* striking unless the liver is involved by metastases or cholangitis or the gallbladder is not functioning In protecting the liver from back pressure however the gallbladder *is itself enlarged in nearly all malignant* obstructions of the common duct but it can be palpated in only half the cases A definite finding of an enlarged nontender gallbladder in a jaundiced patient may therefore be taken as a reliable sign of malignant choledochal obstruction (Courvoisier's law) No diagnostic inference is warranted if the gallbladder is not palpable

In advanced cases abdominal masses enlarged supraclavicular nodes a liver hardened and enlarged by *metastases or evidences of ascites may* be found Splenomegaly does not occur except in the rare case of occlusion of the splenic vein by cancer arising in the pancreatic body or tail In 20 per cent of the cancers at this site spontaneous venous thrombosis of the extremities particularly the legs take place

Laboratory Data The urine blood and feces of nonicteric patients are often normal Those with icterus *manifest persistent and progressive* bilirubinemia and choluria with all the attributes of a regurgitation jaundice (Chap 18) The stools may be greasy abundant of a pultaceous consistence very deficient in bile and most dreadfully foetid (Richard Bright 1833) In at least half the cases however the clay colored stools are not grossly fatty and are more like putty than butter Since bile salts are necessary for the absorption of vitamin K hypoprothrombinemia develops with prolonged biliary obstruction

Since neoplastic cells are in general nonfunctioning and since the functional capacity of surviving *acinar cells is tremendous serum enzyme values are* normal in three fourths of the cases Except in case of very small and nonobstructing lesions the volume of pancreatic juice in response to secretin stimulation is usually reduced Glucose tolerance tests are abnormal in 40 per cent of the cases *but the patient's age or an antecedent* diabetes *may account* for this finding

Because ampullary cancers tend to ulcerate and *form* fistulas between the biliary and alimentary tracts the results of laboratory tests may differ *from those usually obtaining in jaundiced patients* with cancer in the head of the pancreas (Table 128)

Course Pancreatic cancer leads to death by inanition biliary obstruction local extension or *distant metastases By direct extension the cancer* may invade the liver spleen stomach duodenum colon portal venous system or peritoneum Invasion of the gut or development of varices following malignant occlusion of the portal or splenic *vein can cause moderate to severe gastrointestinal* blood loss Peritoneal seeding or very rarely portal obstruction is responsible for ascites Metastatic lesions develop in the regional lymph nodes liver lungs mediastinal and cervical lymph nodes and bones

Diagnosis In jaundiced patients differential diagnosis from liver disease or gallstones depends on the clinical picture and on laboratory tests showing in pancreatic cancer regurgitation jaundice (Chap 18) *and normal hepatic metabolic function* (Chap 18) Favoring pancreatic cancer is a gradual onset of symptoms in elderly patients without antecedent acute malaise intermittent colics or chills and fever *If itching is noticed before jaundice mechanical obstruction of the biliary passages is likely* In early cases before diagnosis is made obvious by massive or metastatic growth cancer is indicated by finding an enlarged gallbladder and a nontender *liver not more than moderately* enlarged and by not finding such stigmas of liver disease as *spider* angiomas dilated abdominal veins and splenomegaly

Radiologic procedures may show the effect of *the pancreatic lesion on other organs* Changes in the mucosa or configuration of the duodenal loop may sometimes appear as early phenomena but secondary gastrointestinal abnormalities are usually signs of advanced disease Application of newer x ray techniques such as aortograms and splenoportograms may at times prove fruitful but intravenous cholangiography will probably be most helpful in those with little icterus and on occasion *percutaneous cholangiography* via the gallbladder in those frankly jaundiced (see Chap 251)

lipemia either persistently or only during the acute attacks

Diagnosis Chronic relapsing pancreatitis is a good diagnostic possibility in all patients suffering from recurrent upper abdominal pain especially if (1) pain and tenderness extend to the left of the midline (2) alcoholism is present or gallstones and (3) more common abdominal disorders have been excluded The disease also may explain mild or recurrent jaundice diabetes or vague symptoms of indigestion particularly if these phenomena are accompanied by low grade fever or a persistently elevated sedimentation rate otherwise unexplained If pancreatic calcification is present its radiologic demonstration permits ready diagnosis but specially positioned oblique views in a patient who has not been given barium in the immediate past may be necessary to demonstrate small calcareous deposits In patients without such calcification diagnosis is best achieved by serum amylase determinations taken within 8 hr of a major attack Repeated attempts may be necessary however for the levels of amylase do not rise with each episode The bicarbonate concentration of secretin stimulated pancreatic juice is said to be reduced in 95 per cent of cases of chronic pancreatitis Absorption tests may reveal impairment of this function but it is not certain that they reveal early or mild disease of the pancreas

Treatment The consequences of pancreatic insufficiency can be controlled with moderate success by dietary restriction of fats and calories and by oral administration of 10 to 20 Gm of pancreatin daily Medical control of pain on the other hand is desultory Manipulation of diet anticholinergics and ulcer type regimens given in the hope of controlling gastric acidity and thereby lessening the stimulus for secretin production are all more or less ineffective ACTH cortisone and similar agents are of doubtful benefit and may cause harm because of their effect on gastric secretion Surgery must therefore be tried when pain is disabling but its results too are far from satisfactory Surgery is most successful if a responsible biliary tract abnormality such as stone can be corrected or if obstruction of a major pancreatic duct exists and can be eliminated by cutting a stenotic sphincter of Oddi removing an obstructing lesion near the sphincter or establishing reverse drainage by resecting the pancreatic tail with anastomosis of the severed duct to the jejunum Vagotomy subtotal gastrectomy to reduce gastric secretion and cutting a normal or spastic sphincter of Oddi to prevent biliary reflux in the pancreatic ducts have produced erratically successful results Bilateral sympathectomy and splanchnicectomy may be used as symptomatic procedures to relieve pain but the relief is only temporary in half the cases If the process is localized partial pancreatectomy may prove successful total pancreatectomy relieves pain but results in other disabilities

FIBROCYSTIC DISEASE

In this perhaps genetically transmitted disorder of infancy and childhood several organ systems are affected (1) The pancreatic acini are replaced by fibrotic tissue multiple cysts and inspissated mucus The clinical manifestations of the consequent pancreatic insufficiency are malnutrition and bulky and greasy stools (2) Somewhat similar pathologic changes affect the lungs so that the patient suffers from obstructive emphysema and is susceptible to chronic bronchopneumonia (3) The sweat and the saliva contain high concentrations of chloride and sodium in hot weather this abnormality may cause acute salt depletion and at times death (4) In a few cases the smaller hepatic biliary channels are plugged with the consequent development of cirrhosis and portal hypertension (5) In the newborn infant a thick meconium presumably viscous because pancreatic juice is absent may cause meconium ileus

The etiology is obscure One hypothesis holds that abnormally viscid mucus blocks small tubular structures in the various organs involved This concept of mucoviscidosis however does not explain the abnormalities of sweat since sweat glands secrete no mucus Diagnosis is made on the basis of the clinical picture deficiency of pancreatic ferments and high sweat electrolytes Treatment consists of pancreatic substitution therapy and antibiotics to control pulmonary infection In severe cases the prognosis is poor but patients with milder cases can survive An adult counterpart or sequel to fibrocystic disease of the pancreas is not recognized

CANCER

Incidence Cancer of the pancreas predominantly affects patients over forty five attacks men twice as frequently as women and accounts for about one out of every two to three hundred deaths It is seen about one tenth as often as gastric cancer in men and one fortieth as often as mammary cancer in women Diabetic patients are believed to have an increased susceptibility to the disease

Symptoms Weight loss pain and jaundice are the outstanding symptoms Digestive disorders including anorexia nausea loose stools or more commonly constipation are prevalent The site of the lesion however to a great extent influences the character of the symptoms their time of onset and their correct interpretation

Considering the total course of all types of pan

cystadenocarcinomas and hemangiomas Benign and malignant growths of the islet cells are discussed in Chap 69

The reader is referred to Chap 5 Acute Abdominal Pain and Ileus Chap 16 Constipation and Diarrhea Chap 18 Jaundice and Disorders of Liver Function Chap 68 Diabetes Mellitus and Chap 95 Disorders of Glycogen Storage for further consideration of problems discussed in this chapter

Section 6 The Liver, Gallbladder, and Bile Ducts

250 DISEASES OF THE LIVER

Gerald Klatskin

In trying to establish the nature of any hepatic disorder it is helpful to begin with a consideration of the probable anatomic localization and morphologic character of the underlying lesion before proceeding to the identification of its etiology Despite the intimate interrelationships between the major functional components of the liver and the tendency for lesions in one to affect the others secondarily it is possible usually to distinguish among diseases that arise in the hepatic parenchyma biliary tree and vasculature In many instances the etiology is unknown while in others the etiology must be inferred from the character of the lesions For that reason a morphologic classification of liver disease (Table 129) is more practical than one based on etiologic factors

To avoid unnecessary duplication the clinical manifestations and functional abnormalities shared by many diseases of the liver are considered together in Chap 18 The latter is intended to serve as an introduction and should be read in conjunction with the discussion of the individual diseases in the section to follow

Table 129 CLASSIFICATION OF LIVER DISEASE

I Parenchymal
- *A* Hepatitis viral toxic associated with systemic infection granulomatous
- *B* Cirrhosis Laennec's postnecrotic biliary cardiac hemochromatosis Wilson's disease rare types
- *C* Infiltration fat iron glycogen amyloid lymphoma Gaucher's disease Niemann-Pick disease
- *D* Space-occupying lesions tumors amebic abscess pyogenic abscess gumma echinococcus cyst
- *E* Functional disorders of unknown etiology constitutional hyperbilirubinemia idiopathic icterus with pigmentation of the liver familial nonhemolytic jaundice of the newborn

II Hepatobiliary
- *A* Extrahepatic biliary obstruction stone stricture malignancy
- *B* Cholangitis

III Vascular
- *A* Chronic passive congestion
- *B* Cardiac cirrhosis
- *C* Budd Chiari syndrome
- *D* Portal vein thrombosis
- *E* Pylephlebitis
- *F* Cruveilhier Baumgarten syndrome

Table 128 CLINICAL FEATURES AND LABORATORY FINDINGS IN CANCER OF THE BILE DUCTS AND PANCREAS

	Cancer of ampulla of Vater	Cancer of bile ducts	Cancer of head of pancreas	Cancer of body and tail of pancreas
Pain	Absent—60% Moderate—40%	Absent—40% Moderate to severe—60%	Absent to mild—15% Moderate to severe—85%	Almost invariably present Agonizing and boring *Often worse in back* and accentuated when patient is supine
Jaundice				
Onset	Early	Early	Variable	Late to terminal
Character	Progressive and marked—80% Fluctuating—20%	Progressive and marked—90% Fluctuating—10%	Progressive and marked	Mild to moderate
Weight loss before onset of jaundice †	None to mild	None to moderate	Occasionally none but often 10 to 20 lb	Marked 10 to 60 lb
Fever and chills	20%	10%	None	May have low grade fever No chills
Hepatomegaly	None to slight	Slight in some cases but may be extreme	Moderate Marked only if metastases present	None to marked Size depends on degree of metastatic involvement
Enlarged gallbladder palpable or visible	50%	20%	50%	0
Splenomegaly	None	None	None	Occasional
Bile in stools and urobilinogen in urine	Absent—80% Fluctuating—20%	Absent—90% Fluctuating—10%	Absent	Present
Occult blood in stool	50%	15%	Rare	Rare

* Because of their anatomic proximity advanced cancers of the ampulla of Vater the bile ducts and the pancreatic head at times cannot be distinguished clinically

† All these cancers cause impressive weight loss sooner or later

When the patient is not jaundiced early diagnosis is difficult particularly since the patient may exhibit psychoneurotic tendencies Persistent pain and progressive weight loss with negative radiologic studies of the alimentary renal and biliary passages should raise the suspicion of pancreatic cancer In *patients with ascites the character of the fluid and* its cellular content often permit the diagnosis of cancer but differential diagnosis from ovarian gastric or primary hepatic cancer is not easy Duodenal drainage may reveal neoplastic cells in the cellular sediment

Treatment Resection of lesions confined to the ampullary area is successful in terms of 5 year cures in 15 per cent of the cases In cancers located elsewhere in the pancreas extensive pancreatic duodenal resection including total pancreatectomy is feasible in many instances but the patient almost invariably succumbs *to local or distant recurrence* In jaundiced patients however palliative anastomosis of the gallbladder to the intestinal tract affords relief from the intolerable itching Before operation is undertaken any existing deficiencies of water electrolytes red cells and vitamin K should be corrected

OTHER CONDITIONS

The pancreas is often involved by mumps but only rarely is pancreatitis the sole manifestation of the disease Like other viscera the pancreas may be affected by periarteritis nodosa

Ectopically placed pancreatic tissue may be found in the gastrointestinal tract Meckel's diverticulum and various other areas Nearly all pancreatic rests radiologically discovered in adult however occur in the distal stomach and duodenum Rarely the rest creates an annular constriction of the duodenum

Unusual pancreatic neoplasms are cystadenomas

tion accounts for the infrequency with which definite exposure to the disease can be established Young children and especially infants appear to be an important reservoir for this type of infection Explosive epidemics may follow exposure to feces contaminated water or food supplies and occasionally infections are acquired by the parenteral route following the transfusion of blood or the use of blood contaminated instruments In many areas infections are more prevalent in the autumn and early winter months but in others there appears to be no seasonal fluctuation

The disease may occur at any age but is most common in children and young adults After the age of thirty the incidence is relatively low apparently because of immunity acquired in early life No doubt this accounts also for the effectiveness of pooled gamma globulin in preventing infection following exposure The immunity that follows infection is usually lifelong in duration but may be less sustained in some individuals so that reinfection is possible

In SH virus infections the virus gains entry to the body by the parenteral route as a result of transfusions or injections of infected blood plasma or serum or the use of improperly sterilized blood contaminated needles syringes or other surgical equipment Occasionally handlers of blood and blood products become infected presumably through nicks in the skin The disease may occur also following the use of topical thrombin However other blood products prepared by the ethanol fractionation method such as gamma globulin serum albumin and antihemophilic globulin appear to be noninfectious Recent evidence suggests that the transplacental transmission of virus to the fetus in pregnant asymptomatic carriers may be responsible for neonatal hepatitis and that this may be an important mode of propagating the virus from one generation to the next

Asymptomatic carriers play a key role in the spread of this disease Estimates of their prevalence are not available but on the basis of the number of infections that follow a single blood transfusion they would appear to comprise approximately 1 per cent of the population Very few of these individuals have had a clinically recognizable infection but some exhibit minor alterations in liver function and a few have significant hepatic lesions suggesting that some carriers at least have active but subclinical disease

Since a large number of bloods is used to make up a single pool of plasma the recipient of a plasma infusion is exposed to numerous potentially infected donors As a result the risk is very much greater than that following a single blood transfusion. The virus may be present in high concentration. In some instances as little as 0 00005 ml is infectious which explains why needles syringes and other instruments inconspicuously contaminated with blood may serve as vehicles for infection

Pathology

The lesions of viral hepatitis which are uniformly distributed throughout the liver are characterized by degeneration and necrosis of parenchymal cells proliferation and swelling of the reticuloendothelium and cellular infiltration of the sinusoids and portal triads Scattered groups of hepatic cells undergo rapid lysis especially in the pericentral areas of the lobules while many of the remaining cells show degenerative changes characterized by ballooning or hyalinization to form densely stained acidophilic bodies Almost from the beginning there are signs of active regeneration including mitotic figures hyperchromatism and numerous binucleate cells As a result of these changes the liver cords are disrupted and distorted leading to disorganization of the normal lobular pattern The intervening sinusoids contain clumps of swollen Kupffer cells and numerous lymphocytes plasma cells wandering macrophages and occasional eosinophils and polymorphonuclear cells A similar exudate is seen in the portal triads Many of the macrophages adjacent to necrotic areas contain lipofuscin a yellow acid fast pigment presumably derived from broken down hepatic cells Occasionally some of the canaliculi are filled with inspissated bile

The reticulum fibers are spared and serve an important function in providing a framework for the orderly reorganization of the lobules As long as the areas of necrosis whatever their size are limited to the confines of the individual lobules local regeneration and restitution of the normal architecture are assured In contrast when the necrotic zones encompass whole lobules this is not possible since regeneration must proceed from distant unaffected lobules This leads to the formation of large regenerating nodules which compress the intervening reticulum of the completely destroyed lobules into bands containing the remaining blood vessels regenerating ducts and exudate This variant of the disease is known as subacute necrosis of the liver Ultimately if the patient survives the collapsed reticulum undergoes collagenization, giving rise to postnecrotic cirrhosis However even in the healed state signs of varying degrees of active parenchymal inflammation and necrosis may be evident for long periods of time When the areas of necrosis are extensive the liver tends to be small and coarsely nodular with broad intervening bands of collapse and fibrosis the usual picture in this type of cirrhosis However if the necrosis involves limited numbers of adjacent lobules a finely nodular cirrhosis may ensue Fine nodulation may occur also as a result of progressive degeneration

PARENCHYMAL

Hepatitis

Viral Hepatitis

Viral hepatitis is an acute systemic infection that affects the liver predominantly giving rise to highly characteristic hepatic lesions The disease occurs in two forms due to closely related but distinct etiologic agents known as *virus IH* and *SH* or *A* and *B* respectively The two infections are indistinguishable on the basis of their clinical and morphologic manifestations but they exhibit differences in their epidemiologic and immunologic behavior The IH type is known as *infectious* or *epidemic hepatitis* the SH type as *homologous serum posttransfusion inoculation* or *syringe transmitted hepatitis* Since both viruses may be transmitted by the parenteral route the terms indicated may be confusing There is a growing tendency therefore to supplant them with the terms IH and SH or A and B viral hepatitis Before the pathogenesis of viral hepatitis was understood the IH type was called *catarrhal jaundice* in the mistaken belief that the symptoms were due to an inflammatory obstruction of the common duct There is no justification for the continued use of this obsolete term

Etiology

The agents responsible for this form of hepatitis have not been identified microscopically or serologically and have not been propagated in tissue culture embryonated eggs or experimental animals However they have been shown to be filtrable through a Seitz EK filter and are readily transmitted to susceptible human volunteers suggesting very strongly that they are viral in nature What little is known about the properties and behavior of these viruses has been derived from transmission experiments in man Since of necessity these experiments have been limited in number there are still a great many gaps in knowledge of the viruses The absence of a susceptible animal host or a suitable serologic technique for identifying these agents has been a stumbling block in the study of viral hepatitis not only for the virologist but also for the clinician pathologist and epidemiologist From a diagnostic point of view the clinician is obliged to depend on clinical and laboratory features which while highly characteristic are never pathognomonic Even the histologic changes in the liver which are more specific cannot be considered unequivocal evidence of infection particularly in the more unusual and late forms of the disease in which the morphologic features are less distinctive

Both the IH and SH viruses are peculiarly resistant to heat (56 C for 30 min and 60 min respectively) prolonged storage in the cold (−10 to −20 C for 1½ and 4½ years respectively) and the action of chemical agents (chlorine 1 1 000 000 for the IH virus and merthiolate 1 2 000 tricresol 2 1 000 and equal parts of phenol and ether 5 1 000 for the SH virus)

The principal differences between the two viruses may be summarized as follows (1) the IH virus has been recovered from both blood and feces the SH virus from the blood only (2) the IH virus may be transmitted to man by either the oral or the parenteral route the SH virus by the parenteral route only (3) the incubation period is 2 to 6 weeks for the IH virus irrespective of the route of administration and from 6 weeks to 6 months for the SH virus (4) the IH virus has been found in the blood from 3 days before to 8 days after the onset of jaundice while the SH virus has been recovered at intervals throughout the long incubation period and during the acute phase of the disease with the rare exceptions to be mentioned in neither case has the agent been demonstrated during convalescence (5) the asymptomatic carrier state appears to be more common and prolonged in the SH type virus having been demonstrated in the blood for periods up to 5 years in individuals with no history of hepatitis the IH type has been recovered from the feces during convalescence in only two instances 4 and 15 months following infection but never from blood or feces in individuals with no history of hepatitis (6) both viruses confer homologous but not heterologous immunity (7) gamma globulin isolated from large pools of plasma collected from randomly selected donors protect against IH but not against SH infection (8) IH infections occur at an earlier age tend to be less severe and are more likely to be accompanied by preicteric constitutional symptoms

It is still not clear whether these two types of virus represent distinct species or merely strain variants of the same species Moreover it is not known whether all the strains belonging to each type are antigenically identical Clinical and epidemiologic studies and transmission experiments have failed to demonstrate any significant differences between the behavior of the strains of each type isolated in various areas of the world However more precise information will have to await the development of better methods of isolating and identifying these agents

Epidemiology

IH viral hepatitis occurs both sporadically and in epidemic form The latter is seen particularly under conditions of crowding and poor sanitation Infection is usually acquired through the oral route by close personal contact with individuals passing virus in their feces It is presumed that the occurrence of many unapparent infections in the popula

Characteristically the jaundice increases rapidly reaching a maximum in 3 to 14 days and then recedes at a somewhat slower rate clearing up completely in 1 to 6 weeks If the serum bilirubin level is followed closely it can be shown that in typical cases there is no plateau at the peak although one may occur during convalescence as the serum bilirubin approaches the normal concentration The intensity of the jaundice at its maximum tends to mirror the extent of the hepatic damage so that usually it provides some indication of the expected severity and duration of the disease However there are many exceptions minimal jaundice therefore does not exclude the possibility of severe hepatic injury nor does deep jaundice necessarily imply a protracted or severe illness

Immediately following the subsidence of jaundice the patient usually feels well but recovery is seldom complete at this stage The liver may be enlarged and tender abnormalities of hepatic function are often evident and histologic studies usually show incomplete resolution of the lesion Of even greater importance resumption of full activity at this time may precipitate a relapse with a recrudescence of any or all of the previous symptoms The duration of this *posticteric phase* varies from 2 to 6 weeks but may be longer in some instances However full clinical and biochemical recovery is to be expected within 4 months

Laboratory Features The *leukocyte count* is normal but may be low during the preicteric phase Occasionally atypical lymphocytes indistinguishable from those of infectious mononucleosis are present in small numbers The *sedimentation rate* is high in the preicteric stage falls to normal during the icteric stage and rises again during convalescence

The *urine* may contain traces of bilirubin even before jaundice appears As jaundice deepens the amount of bilirubin increases but during convalescence bilirubin excretion often ceases before the serum bilirubin has returned to normal During the preicteric phase urine urobilinogen may be increased but as jaundice and light colored feces appear the amount of urobilinogen falls to the normal level Often a secondary increase in urine urobilinogen occurs when the jaundice begins to fade and the stools return to their normal color Finally the level falls to normal when recovery has occurred

Early in the course of the jaundice the stools may be light or clay-colored for a few days to a week Later their appearance is normal In many cases there is no change in color despite the presence of overt jaundice

The *direct and total serum bilirubin* levels rise and fall together and reflect the depth of jaundice The direct fraction usually constitutes 50 to 75 per cent of the total early in the course of the disease but may be relatively lower later An increase in the direct fraction without a concomitant rise in the total bilirubin may be seen both in the preicteric phase and late in convalescence In a few individuals the indirect fraction remains slightly elevated for long periods following apparent recovery

Bromsulphalein retention is increased during the preicteric phase and remains so for some time after the subsidence of jaundice It returns to normal when healing is complete but occasionally mild retention persists despite apparent full recovery

The *cephalin cholesterol flocculation* and *thymol turbidity* tests usually become positive toward the end of the preicteric phase or shortly thereafter They tend to revert to normal late in convalescence but often persist for long periods following apparent recovery Occasionally one or both tests remain normal throughout the course of the disease

The *serum alkaline phosphatase* level tends to rise slightly but occasionally it reaches the concentration seen in extrahepatic obstructive jaundice

The *serum protein pattern* is normal early in the disease but may show a fall in albumin and a rise in globulin if the disease is prolonged or severe

Usually the *serum cholesterol concentration* is normal but during the icteric phase the percentage of esters tends to fall In a few individuals a high total cholesterol is seen transiently during the phase of increasing jaundice

Diagnosis During the preicteric phase viral hepatitis may be difficult to differentiate from a number of other infections but marked anorexia out of proportion to the degree of fever subcostal tenderness and the occurrence of dark urine should alert the clinician to the possibility of viral hepatitis and call for investigation of the liver by appropriate tests

Once jaundice has appeared it becomes necessary to exclude other forms of hepatitis an exacerbation of a chronic hepatic disorder and extrahepatic biliary obstruction A careful history will usually suffice to rule out toxic and drug hepatitis but the appearance of renal failure or signs of a hypersensitivity reaction should call for further inquiry Marked myalgia nuchal rigidity conjunctival injection and leukocytosis should suggest the possibility of leptospirosis A severe sore throat and marked cervical adenopathy may be indicative of infectious mononucleosis with jaundice The presence of spider nevi ascites or edema early in the disease usually denotes an underlying cirrhosis but later it may be indicative of subacute necrosis of the liver Shaking chills colicky pain significant leukocytosis and a past history of dyspepsia usually point to a common duct stone

Even in the most typical case of viral hepatitis

and collapse of large nodules because of either continued inflammatory activity or the tendency of the nodules to outgrow their circulatory supply At this stage it may be difficult to distinguish the lesion from that of Laennec s cirrhosis

Occasionally the hepatitis virus produces *massive necrosis of the liver* In this condition there are large areas of necrosis and collapse as in subacute necrosis but death ensues before signs of regeneration appear Since the liver tends to shrink in size and is often bile stained at least early in the disease the lesion was once termed *acute yellow atrophy*

It should be noted that while the hepatitis virus is the most common cause of subacute and massive necrosis certain drugs and poisons are capable of producing a very similar lesion

Although restoration of the normal architecture and resolution of the inflammatory reaction are the rule following recovery from *uncomplicated* viral hepatitis mild degrees of periportal fibrosis and round cell infiltration are common residuals They bear no relationship to the minor symptoms and alteration in function that may be present at this time and are *not* to be interpreted as evidence of chronic hepatitis

Clinical Manifestations

Usually the clinical manifestations follow a highly characteristic pattern and subside without residuals within a period of 4 months For purposes of identification and further discussion this form of the disease will be designated as *typical acute viral hepatitis* In approximately 15 per cent of patients the clinical course is atypical in that it terminates fatally is greatly prolonged or is characterized by unusual manifestations These features are sometimes considered complications of the disease but it should be emphasized that the basic lesion is the same in all instances

The mortality rate based usually on the number of fatalities from subacute and massive necrosis that occur within the first few months of the disease is said to lie between 0 2 and 0 4 per cent This does not take into account the late deaths that follow residual postnecrotic cirrhosis However since the number of unrecognized mild and non icteric infections is probably large the over all mortality rate may be considerably lower than that indicated

Little is known about the factors responsible for the variations in the severity and clinical course of viral hepatitis Complicating malnutrition alcoholism intercurrent infection physical exhaustion and inadequate therapy are thought to be important but the evidence implicating these factors is inconclusive The severity of the disease and its mortality rate appear to be greater in older persons and in those infected with the SH virus possibly because of the higher incidence of complicating disease in such individuals

Typical Acute Viral Hepatitis

Symptoms and Signs In approximately 80 per cent of IH but in only 20 per cent of SH viral infections the onset of jaundice is preceded by a period of nonspecific constitutional and gastrointestinal symptoms that may last from a few days up to 2 weeks Often these symptoms are mistaken for signs of a respiratory infection or acute gastroenteritis

Usually the onset of the *preicteric phase* is abrupt *Fever* marked *anorexia* and *weakness* are the outstanding symptoms and often a sudden distaste for cigarettes is a striking feature These symptoms may be accompanied by nausea and vomiting indigestion abdominal pain headache pain on moving the eyes arthralgia and myalgia Occasionally there is an erythematous or urticarial rash As a rule the fever is remittent and only moderate in degree but in severe infections it may be high and associated with marked prostration Chilly sensations are relatively common in such cases but *frank shaking chills are rare* When abdominal pain is present it is usually dull and aching in character and located in the epigastric area or right upper quadrant Rarely it is severe and may be accompanied by marked abdominal tenderness and spasm suggesting an acute surgical emergency In some individuals upper respiratory symptoms are a prominent feature

Often at this stage the liver is slightly enlarged and tender but even if it is not percussion over the hepatic region may provoke pain In about 20 per cent of patients a mild degree of splenomegaly can be demonstrated and in a somewhat smaller number the posterior cervical lymph nodes are enlarged

Within a few days to a week of the onset and sometimes even before the appearance of jaundice the urine darkens owing to the presence of bilirubin This may be the first clue to the true nature of an otherwise obscure febrile illness Usually icterus of the skin and sclerae becomes evident within a day or two

Early in the *icteric phase* the jaundice deepens hepatic enlargement and tenderness become more evident and the patient s general condition worsens However within a few days the fever and preicteric symptoms usually abate even though the icterus is still increasing Occasionally the fall in temperature and clinical improvement coincide with the appearance of clinical jaundice but in severely ill patients prostration anorexia nausea and vomiting may persist or even increase after subsidence of the fever Unless measures are taken to maintain food intake marked weight loss may ensue

coma Not infrequently the serum albumin falls and the globulin increases. When the clinical course is prolonged, hyperglobulinemia may be extreme As hepatocellular function fails the serum cholesterol may fall to abnormally low levels.

Terminally the patient lapses into hepatic coma and dies of advanced hepatocellular failure How ever in patients with a prolonged course death may be due to intercurrent infection or massive bleeding from esophageal varices

"Cholangiolitic" Hepatitis Occasionally patients with a typical onset of acute viral hepatitis develop clinical and laboratory features suggestive of biliary obstruction. It has been postulated that the inflammatory reaction in such cases involves the terminal perilobular cholangioles permitting the regurgitation of bile as a result of compression by exudate or abnormal permeability For that reason the syndrome has been called *cholangiolitic* hepatitis However there is no histologic evidence that the cholangiolar involvement is any more severe or qualitatively different from that in the usual form of hepatitis so that the theory of increased cholangiolar permeability or obstruction rests solely on circumstantial clinical evidence Most pathologists do not consider "cholangiolitic" hepatitis a distinct pathologic entity but the unusual clinical manifestations of the syndrome warrant its classification as an atypical variant of acute viral hepatitis

The distinctive features of the disease are prolonged jaundice often accompanied by pruritus significant hepatomegaly a sustained and marked increase in the percentage of direct reacting serum bilirubin, high levels of serum alkaline phosphatase and cholesterol, and a negative or only weakly positive cephalin-cholesterol flocculation reaction Usually the serum albumin concentration is normal or only slightly depressed but the globulin fraction is almost always increased Early in the disease the histologic features are indistinguishable from those of typical acute viral hepatitis but later they may be difficult to differentiate from those of an extrahepatic biliary obstruction the principal findings being bile staining of the parenchyma intracanalicular bile thrombi and a mononuclear periportal exudate without hepatocellular changes

Except for unusual fatigability and pruritus the patient often feels remarkably well and goes on to an uneventful recovery after a period of sustained or fluctuating jaundice lasting from a few months to a year In some instances however the disease appears to be progressive giving rise to cholangiolitic cirrhosis an entity thought to be closely related to primary biliary cirrhosis (p 1508)

The differentiation between cholangiolitic hepatitis and extrahepatic biliary obstruction may be exceedingly difficult even after the most exhaustive investigation including liver biopsy so that exploratory laparotomy may be necessary However a careful history will often reveal the typical symptoms of viral hepatitis at the onset, and the results of liver function tests carried out early in the course of the disease are likely to be more typical of hepatocellular disease Certain drugs and particularly chlorpromazine (Thorazine) and methyltestosterone are capable of producing an identical picture It is essential, therefore that the possibility of a drug reaction be excluded with certainty in all instances of suspected "cholangiolitic" hepatitis.

Sequelae

Occasionally signs or symptoms of liver disease persist or recur beyond the 4-month period during which recovery is to be expected. This may be because of slow resolution and healing, progressive inflammation and destruction of the parenchyma, postnecrotic scarring functional disorders of the parenchyma, or even complicating psychogenic disturbances. It is misleading therefore to classify all forms of delayed recovery as "chronic viral hepatitis Moreover the term has the additional disadvantage that it is sometimes used in a more specific sense to indicate posthepatitic cirrhosis or chronic parenchymal destruction leading to cirrhosis Wherever possible an attempt should be made to determine the anatomic and physiologic basis for the persistence of abnormal findings. Unfortunately this is not always feasible without resort to liver biopsy but prolonged observation and serial laboratory studies often suffice to distinguish between the several types of prolonged or recurrent hepatitis to be discussed

Minor Residuals without Clinical Significance A significant number of patients with acute viral hepatitis exhibit minor abnormalities of hepatic function or slight nontender hepatomegaly for periods of several months to a year following apparent clinical recovery Slight increases in thymol turbidity and cephalin cholesterol flocculation are the most common findings but serum bilirubin levels of 1.2 to 2 mg per 100 ml and Bromsulphalein retention of 6 to 10 per cent are not rare Liver biopsy in this group invariably reveals complete healing It should be noted however that both in this group and in patients without residuals the portal triads may show a mild degree of fibrosis and mononuclear cellular infiltration. In the absence of parenchymal changes there is no evidence that either the histologic or functional residuals described are forerunners of progressive disease or relapse

Prolonged Convalescence In this group any or all of the clinical or laboratory features of the acute disease may persist for long periods, but usually full recovery ensues within a year On histologic examination the liver shows incomplete healing of the parenchymal lesions as in the convalescent

the clinical course should be scrutinized with care since any deviation from the usual pattern may indicate an error in diagnosis or the occurrence of a complication The particular points to note are the duration of the preicteric phase the time it takes for jaundice to reach its maximum the presence or absence of a plateau at the peak of the serum bilirubin curve and the occurrence of ascites edema or spider nevi

Variants of Acute Viral Hepatitis

Acute Anicteric Hepatitis A number of individuals infected with the hepatitis virus fail to develop jaundice In some patients the clinical features are otherwise identical with those of the icteric form of the disease although they tend to be somewhat milder However there is reason to believe on the basis of transmission experiments that the disease may present as a nonspecific illness without localizing signs In infants and young children a mild gastroenteritis or diarrhea may be the only manifestation Liver function tests may show the same pattern seen in icteric hepatitis but often the changes are less striking Occasionally the direct and total serum bilirubin levels are slightly elevated and traces of bile can be demonstrated in the urine

Diagnosis is difficult in this group unless an epidemic is in progress or the clinical and laboratory features closely resemble those of the icteric form of the disease Under other conditions the diagnosis can seldom be made with confidence since the symptoms and changes in liver function are nonspecific

The high incidence of immunity to IH virus infections in adults with no history of hepatitis suggests that anicteric infections are common However relatively few are recognized clinically

Fulminant Hepatitis (Massive Necrosis of the Liver) This form of the disease is usually fatal within 10 days some deaths occurring as early as the second day In the preicteric and early icteric phases the clinical and laboratory features may be identical with those in the more benign type However nausea vomiting and abdominal pain tend to be more severe and jaundice is likely to appear earlier and to deepen more rapidly Usually the first clue of an impending fatal outcome is the appearance of cerebral manifestations indicating the onset of hepatic coma Occasionally the disease is ushered in with neurologic manifestations and progresses rapidly to deep coma and death Other features seen in many but not all cases include a sharp terminal rise in temperature significant leukocytosis a rapid decrease in the size of the liver coffee grounds vomitus or gross hemorrhage into the gastrointestinal tract purpura and ascites Terminally the patient lapses into deep coma and may exhibit muscular twitchings convulsions shock oliguria and azotemia Occasionally the course of the disease is so rapid that death occurs before jaundice develops It may be difficult to establish the diagnosis in such cases unless the possibility of viral hepatitis is considered and appropriate laboratory studies are carried out

Subacute Hepatitis (Subacute Necrosis of the Liver) The clinical course in subacute necrosis of the liver varies depending on the extent of the necrosis the degree of healing and the amount of regeneration As in the fulminant form of the disease the illness often begins as an uncomplicated viral hepatitis only to go on to progressive hepatic failure and death Many patients die within 2 to 12 weeks but some survive for a period of a year or more and a few go on to apparent clinical recovery In the latter group postnecrotic scarring and cirrhosis are inevitable but the outcome depends on the activity of the associated parenchymal inflammatory process and the degree of portal hypertension that develops Relapses with jaundice and other signs of hepatic failure are common in those with active inflammatory lesions and may terminate fatally after one or more such episodes Not infrequently the first recognizable signs of subacute necrosis of the liver make their appearance during a relapse following what was believed to be an uncomplicated attack of acute viral hepatitis There is reason to believe that the apparent progression in such cases merely represents the recrudescence of a lesion incurred during the initial infection Occasionally the same picture is seen following an attack of anicteric hepatitis In cases with postnecrotic scarring there may be a long asymptomatic interval between the initial infection and the accidental discovery of cirrhosis or the occurrence of bleeding from esophageal varices Biopsy studies of the liver indicate that mild forms of subacute necrosis and postnecrotic fibrosis occur more frequently than is evident clinically It is possible therefore that viral hepatitis may be responsible for many instances of cirrhosis discovered years after the initial infection

The clinical features that should suggest the possibility of subacute hepatic necrosis in patients with acute viral hepatitis include (1) jaundice that increases progressively for more than 2 weeks remains stationary at a high level or shows recurrent remissions and relapses (2) fever and leukocytosis that appear after jaundice has developed (3) ascites edema and numerous large spider nevi (4) the appearance of splenomegaly late in the course of the disease (5) severe and persistent vomiting particularly if accompanied by coffee grounds vomitus (6) severe abdominal pain (7) a hemorrhagic tendency as evidenced by epistaxis hematemesis melena hematuria or purpura and (8) fetor hepaticus and other signs of impending

derived from bed rest in the more prolonged forms of viral hepatitis An attempt should be made therefore to determine when maximum benefit has been achieved This can be accomplished by delaying ambulation until the levels of serum bilirubin and Bromsulphalein retention have been stable for at least a week The patient is then allowed increasing activity under supervision If there is any tendency for the clinical signs or laboratory abnormalities to worsen bed rest should be resumed

Diet Patients with viral hepatitis may lose considerable weight If this is prevented by feeding sufficient calories convalescence may be shortened *An intake of 2500 to 3000 cal* is usually adequate but this may be difficult to achieve for short periods during the acute phase of the disease particularly if parenteral feeding becomes necessary

The *optimal protein requirement* is still a matter of debate Many including the author believe that positive nitrogen balance can be achieved with an intake of 70 to 100 Gm and that the regenerative rate of the liver cannot be accelerated by providing an excess However in the military study previously mentioned an intake of 150 to 200 Gm appeared to shorten the period of convalescence significantly but these results are difficult to reconcile with those previously reported by others Except in patients with subacute or massive hepatic necrosis and impending coma in whom the protein intake must be sharply curtailed there is no harm in forcing protein to this extreme but it is difficult to do so and the physician need not be alarmed if he fails

The *fat content* of the diet need not be limited There is no evidence that fats are harmful and indeed, they are useful in enriching the caloric value and palatability of the diet However while milk butter and eggs are usually well tolerated fried and cooked fats often produce gastrointestinal distress and therefore should be restricted

Once the protein requirement has been satisfied and fat has been added as tolerated the remaining caloric needs are made up with *carbohydrate* A high carbohydrate intake has no special virtue and the outmoded practice of forcing sweets throughout the day is to be condemned since it often spoils the patient s appetite for other foods and may provoke fatty infiltration of the liver if the patient s protein intake is not increased proportionately

There is no convincing evidence to show that vitamin supplements are of value in the treatment of viral hepatitis although they may be indicated if there was antecedent malnutrition or if prolonged parenteral feeding becomes necessary Similarly there is no logical reason for adding lipotropic substances like choline and methionine to a balanced diet particularly since fatty infiltration is not a feature of viral hepatitis

Severe anorexia, nausea and vomiting may necessitate resort to parenteral feeding A slow drip of 15 per cent glucose providing from 300 to 400 Gm per day will usually suffice to maintain the patient in a reasonable state of nutrition and hydration over the brief period usually required before oral feedings can be resumed The amount of sodium potassium and chloride to be added to the solution will depend on the losses in the urine feces vomitus and sweat and may be estimated from the state of hydration and the serum electrolyte pattern Parenteral amino acid supplements have been advocated but there is no evidence that they are of special benefit Moreover they frequently cause reactions and are contraindicated in patients with impending coma

Antibiotics The antibiotics do not appear to be of any value in the treatment of acute viral hepatitis However broad spectrum antibiotics may be useful in the management of coma complicating massive and subacute hepatic necrosis Also it has been reported that chlortetracycline (Aureomycin) hastens recovery in patients with prolonged convalescence although the evidence for this is not very convincing

ACTH and Cortisone These agents are capable of inducing a prompt clinical remission in acute viral hepatitis However the length of the convalescent period is not shortened in the uncomplicated form of the disease and relapses are common unless treatment is prolonged It is deemed inadvisable therefore to subject patients to the possible hazards of ACTH and cortisone therapy unless there are clear cut indications for it. Certainly this form of treatment is warranted when the symptoms are severe and do not respond to conservative measures and when there are signs of subacute hepatic necrosis There is a clinical impression that the duration of the disease is shortened and that residual lesions are minimized under these conditions but the evidence for this is still inconclusive Not infrequently a course of steroid therapy is effective in terminating prolonged convalescence particularly in patients with chronic "cholangiolitic" hepatitis and occasionally large doses appear to be lifesaving in comatose patients with massive hepatic necrosis Although it is worth trying these agents in the treatment of postnecrotic cirrhosis with evidence of active inflammatory disease the results are usually disappointing and complications are frequent

In using ACTH and cortisone treatment should be continued until the serum bilirubin drops to a normal level or reaches a stable plateau but in either event for a period of not less than 3 weeks In acutely ill patients an infusion of 25 units of ACTH daily administered over an 8- to 10-hr period appears to yield the most satisfactory results although intramuscular cortisone acetate in doses of

stage of the uncomplicated form of the disease In the writer's experience this lesion shows no tendency to progress to subacute necrosis of the liver or to posthepatitic cirrhosis However it is in this group that recrudescences may occur either spontaneously or following premature return to full activity

Subacute Hepatic Necrosis and Posthepatitic Cirrhosis Before signs of overt hepatic failure or portal hypertension appear it may be impossible to distinguish between the clinical and laboratory manifestations of persistent liver disease due to subacute hepatic necrosis and posthepatitic cirrhosis and those due to prolonged convalescence from the uncomplicated form of viral hepatitis However the two can be differentiated readily on the basis of their histologic features

Relapses and Recurrence Not infrequently there is a transient recurrence of symptoms or an increase in functional abnormalities during convalescence Usually this is the result of premature ambulation and resumption of full activity but it may occur also without provocation The manifestations may be identical with those of the initial attack or even more severe but usually they are milder and of shorter duration When the interval between the two attacks is less than 6 months the recurrence almost invariably represents a recrudescence of an unrecognized incompletely healed lesion of either the prolonged convalescent or subacute necrotic type The possibility of reinfection with the heterologous strain of the hepatitis virus or of an error in diagnosis must be considered when the interval is longer However the relapses in posthepatitic cirrhosis which may resemble those of acute hepatitis often occur at long intervals

Posthepatitis Syndrome Occasionally patients complain of unusual fatigability vague discomfort in the right upper quadrant anorexia and indigestion for long periods following complete subsidence of all clinical laboratory and histologic evidence of active liver disease Psychogenic factors are thought to be responsible for this syndrome However in the writer's experience the syndrome is rare in individuals who have had adequate bed rest during convalescence which suggests that it may represent a type of postinfectional asthenia

The Carrier State The importance of carriers in the spread of viral hepatitis has been touched on under Epidemiology Only rarely does the carrier state follow a clinically recognizable attack of acute viral hepatitis which suggests that it is usually the result of an asymptomatic infection However in a few instances virus has been recovered from the feces of infants convalescing from a prolonged but mild illness Since parenteral injections can hardly account for the unusually large number of SH virus carriers in the population serious consideration must be given to the suggestion that the virus may be acquired transplacentally before birth The question of whether the carrier harbors the virus in a diseased liver or merely permits its propagation without incurring any hepatic injury is still under study A significant number of carriers show minor abnormalities of hepatic function and in a few significant histologic changes have been demonstrated in the liver However many carriers show no clinical chemical or histologic evidence of liver disease

Treatment

Rest It is the opinion of many that strict bed rest is indicated until the signs of active hepatic disease have subsided However on the basis of a recent experimental study carried out under carefully controlled conditions in military personnel it has been recommended that patients be allowed up as soon as the acute symptoms abate and that further physical activity be limited to the confines of a hospital ward until full recovery ensues It is difficult to reconcile the results of this investigation with the experience of most clinicians indicating that the incidence of recrudescences prolonged convalescence and postinfectional asthenia is significantly reduced by enforced bed rest Until this difference of opinion is resolved the clinician would be well advised to err on the side of conservatism particularly since complete bed rest does not entail any greater loss of time from work than limiting activity to the confines of the patient's home or hospital ward Moreover the increase in the length of time required for recuperation following a regime of strict bed rest reported in military personnel has not been observed in civilian patients

The patient may be allowed out of bed when (1) all symptoms have subsided (2) the liver is no longer significantly enlarged or tender and (3) the levels of total serum bilirubin and Bromsulphalein retention have fallen below 2 mg per 100 ml and 10 per cent respectively Residual abnormalities in cephalin cholesterol flocculation and thymol turbidity may be disregarded Activity should be increased slowly and a close watch kept for signs of clinical or laboratory relapse If these signs appear bed rest should be reinstituted Resumption of full activity is permitted when the patient's strength has returned to normal In those with residual hepatomegaly or minor alterations in liver function further follow up studies at monthly intervals are advisable The physician should exercise great care in reassuring the patient that such studies are a precautionary measure and that most minor residuals have no clinical significance For that reason it is unwise and usually unnecessary to limit the patient's activity or diet during this period

Obviously there are limits to the benefits to be

vating essential protoplasmic enzyme systems In contrast most drugs that produce hepatic injury such as cinchophen and the sulfonamides exert their effects by inducing a hypersensitivity reaction However a few like chloroform are truly hepatotoxic while others such as the arsenicals may behave both as hepatotoxins and sensitizing agents A number of parenterally administered drugs once considered hepatotoxic because of their apparent tendency to produce jaundice are now known to serve as innocuous vehicles in the transmission of the hepatitis virus by means of inadequately sterilized blood contaminated syringes The type of hepatitis that accompanies certain systemic infections and metabolic disturbances is thought to be the consequence of an endogenous intoxication However little is known about the nature of the presumed toxins involved or the manner in which they exert their deleterious effects so that this form of hepatitis will be considered separately

Local circulatory disturbances and hypoxia may be important contributory factors in the pathogenesis of toxic hepatitis In addition the nutritional status the synergistic effects of alcohol and infection the presence of preexisting liver disease and differences in individual susceptibility may modify the actions of hepatotoxins and sensitizing agents According to some authorities hepatotoxins exert their deleterious effects on the liver by inducing a specific deficiency of essential nutriments such as cystine However there is little convincing evidence that this is a factor in any of the forms of toxic hepatitis seen in man

The clinical and pathologic features of the hepatitis produced by hepatotoxins and sensitizing agents are sufficiently different to warrant their consideration as separate entities Since space does not permit a detailed discussion of the individual agents in each group Table 130 is appended at the end of this chapter to indicate their probable mode of action Accidental transmission of the hepatitis virus while not a factor in the pathogenesis of toxic hepatitis is included since its importance in many forms of drug induced hepatitis is often overlooked Obviously any parenterally administered drug may serve as a vehicle for the hepatitis virus but only those which have been implicated frequently or have been erroneously considered hepatotoxins are indicated in the table

Toxipathic Hepatitis Characteristically the liver lesions produced by true hepatotoxins make their appearance within a day or two of exposure are readily reproducible in most if not all species and exhibit morphologic features distinctive for each of the agents In many instances there are accompanying toxic lesions in other organs especially in the kidney

The *histologic changes* in the liver vary not only with the agent involved but also with the dose and route of administration In general however the acute lesions tend to be distributed uniformly throughout the lobules in either a central or a periportal zonal pattern and they show all stages of parenchymal degeneration from simple swelling to acute necrosis with little or no inflammatory reaction Often fatty infiltration is a prominent feature Usually the lesion is reversible but death may occur before healing takes place Some poisons such as the *Amanita phalloides* toxin and the chlorinated naphthalenes produce subacute and massive hepatic necrosis which if not fatal leads to the development of postnecrotic cirrhosis Even the agents that produce reversible lesions such as carbon tetrachloride may give rise to cirrhosis if the exposures are repeated at close enough intervals to prevent normal healing

Usually the *clinical picture* resembles that of acute viral hepatitis except for the absence of preicteric fever and constitutional symptoms Anorexia nausea and vomiting are the principal symptoms while jaundice and hepatomegaly are the major physical findings It should be noted however that significant liver damage may occur without producing jaundice The *laboratory features* also are similar to those in viral hepatitis although the changes in cephalin cholesterol flocculation and thymol turbidity tend to be less striking

In addition to the symptoms of liver injury there may be others referable to the extrahepatic pharmacologic and toxic effects of the offending agent Often it is difficult to distinguish between these two groups but renal failure and severe gastrointestinal irritation usually are due to extrahepatic lesions

As a rule recovery occurs more rapidly and residuals are less common than in acute viral hepatitis However subacute or massive hepatic necrosis may be fatal or may give rise to postnecrotic cirrhosis Occasionally death occurs as a result of an accompanying renal lesion despite satisfactory healing of the liver

The *diagnosis* is seldom difficult However errors are inevitable unless a specific inquiry about possible exposure to hepatotoxins is made in every case of hepatitis The sudden occurrence of oliguria and azotemia during an attack of acute hepatitis should always arouse suspicion of an intoxication even if there is no history of exposure particularly since poisoning may occur without the patient s knowledge

Treatment is very much like that described for acute viral hepatitis However greater consideration must be given to the status of the kidneys since hepatotoxins not infrequently produce acute renal tubular necrosis In such cases measures designed to reduce nitrogen retention and to attain a normal internal environment take precedence over

200 to 300 mg per day may be equally effective in some instances If the expected response is not obtained the dose of ACTH may be increased to 50 units As soon as the patient shows marked improvement usually in 2 or 3 days the dose of ACTH is reduced to 10 units and ultimately to 5 units To avoid the inconvenience of repeated infusions oral cortisone may be substituted for ACTH at any time during convalescence Similarly in less acutely ill patients cortisone may be used from the beginning starting with large doses and reducing them as rapidly as the clinical condition permits As indicated elsewhere sodium and potassium intake must be regulated and a watch must be kept for signs of toxicity There may be some advantage in substituting prednisolone for cortisone to minimize salt and water retention However experience with the former in the treatment of acute viral hepatitis is still rather limited

In the fulminant form of the disease with coma doses of cortisone up to 1 000 mg daily have been recommended However too few cases of this type have been treated in this manner to know whether massive therapy has any advantage over the usual dose levels employed

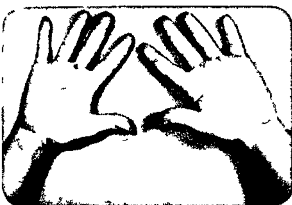
Treatment of Postnecrotic Cirrhosis and Its Complications The problems of therapy in this condition are very similar to those in Laennec s cirrhosis (p 1503)

Prevention

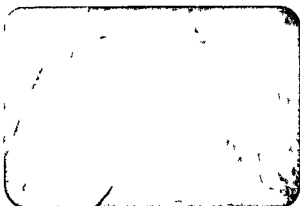
Since the patient with an IH viral infection passes the virus in his stools the usual sanitary measures employed in other enteric diseases must be initiated to prevent spread of the infection to others Unfortunately the duration of fecal infectivity is not known so that precise recommendations cannot be made regarding the length of the period during which precautionary measures must be followed However it is customary to carry them out until clinical recovery has been achieved

The blood is a source of infection in both types of viral hepatitis so that special care must be taken to avoid the transfer of virus to other patients through the agency of improperly sterilized blood contaminated instruments Preliminary washing followed by boiling for 10 min or preferably autoclaving for 15 min will ensure destruction of the virus The practice of using a single syringe with a change of needles for multiple injections in groups of patients is dangerous and is to be condemned

The selection of donors in blood banks is a difficult problem It is customary to eliminate individuals who have had viral hepatitis within a year However such persons appear to be a less danger ous source of infection than asymptomatic carriers with no history of previous disease Unfortunately there is no assured method of detecting such individuals but there is suggestive evidence that the incidence of abnormal liver function test results is unusually high in this group so that there is some hope that by screening all bloods by some simple technique such as the thymol turbidity test it may be possible to reduce the number of hazardous donors However some infected donors will escape detection and the number of presumably safe donors that must be rejected is so large that few blood banks have adopted this procedure Various methods of chemical treatment have been recommended to sterilize blood but none has proved satisfactory Since the possibility of infection cannot be eliminated with certainty the clinician would be well advised to limit the use of transfusions to conditions in which they are unequivocally indicated



Commercially available plasma is even more dangerous than blood since large numbers of donors are used in making up a single pool If plasma must be used it should be obtained from as small a pool of donors as possible There is suggestive evidence that storage of plasma in the liquid state at room temperature for periods of 6 months or longer greatly reduces the risk of infection but other methods of sterilization that have been recommended are of little value



Individuals exposed to the IH type of viral hepatitis may be immunized passively by administering normal human gamma globulin at any time up to within 6 days of the expected onset of the disease The usual dose is 10 ml However recent evidence suggests that with very much smaller doses 0 01 ml per lb body weight it may be possible to achieve a more prolonged type of active passive immunity It is believed that under these conditions the gamma globulin suppresses the symptoms but does not prevent infection so that a natural acquired immunity develops It is doubtful that gamma globulin is of prophylactic value in SH viral infections although it has been reported that two injections of 10 ml each given at monthly intervals may be partially protective

Although gamma globulin is of particular value in the control of institutional and family epidemics there is no reason why it should not be used in any individual who has been exposed However the disease is so mild in healthy young children that it may be better to allow them to become infected and acquire a natural immunity

Toxic Hepatitis

The type of liver injury known as toxic hepatitis occurs following exposure to certain poisons and drugs or during the course of some systemic infections and metabolic disturbances True hepatotoxins such as carbon tetrachloride and phosphorus are tissue poisons that damage the liver by inacti

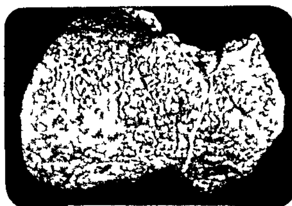


PLATE IV

(*A*) Hands of a 56 year old patient with portal cirrhosis held overhead showing liver palms with erythema of thenar and hypothenar eminences and finger pads (*B*) Numerous spider angiomata scattered over the right shoulder area of the same patient Note large solitary spider with central body and hairlike feet (*C*) Gross appearance of liver of same patient showing fine even nodularity or hob nailing and shrunken appearance (*D*) Same specimen in cut section showing even size of nodules and yellow color of increased fat content (*E*) Microscopic section (Masson stain) Note thickness of liver capsule increased amount of fibrous tissue in portal area and presence of fatty infiltration (*F*) Healed toxic cirrhosis (postnecrotic cirrhosis) following acute infectious hepatitis and chronic active hepatitis Note great thickness of connective tissue bands and isolation of parenchyma into small concentric hyperplastic nodule A mild inflammatory cellular infiltration persists and the small bile ducts show active hyperplasia Fat is inconspicuous

the less urgent needs of the liver This usually entails marked restriction or actual omission of protein provision of sufficient carbohydrate and fat calories to minimize protein catabolism and careful regulation of fluid and electrolyte balance

Hepatitis Due to Drug Hypersensitivity The features that characterize this type of hepatic damage and serve to distinguish it from that produced by true hepatotoxins include the following (1) the hepatitis occurs in only a small proportion of individuals exposed (2) neither the incidence nor the severity of the injury can be correlated with the amount of drug consumed (3) the lesion is not reproducible in animals (4) the onset of hepatitis bears no constant temporal relationship to the institution of drug therapy occurring with dramatic suddenness after the first dose in some individuals and only after prolonged administration or even following its withdrawal in others (5) the lesions are more variable than in toxipathic hepatitis and (6) signs of liver disease often are accompanied by other manifestations of hypersensitivity

Two generalizations are worth bearing in mind in interpreting the role of drugs in the pathogenesis of hepatitis (1) if a drug produces liver injury in man but fails to do so in other species it almost certainly is a sensitizing agent (2) if a drug gives rise to any other manifestations of hypersensitivity it can be predicted that sooner or later it will produce hepatitis in some individuals

Experimentally it has been shown that simple chemical compounds by combining with proteins may serve as antigens and induce hypersensitivity Similarly the striking clinical similarities between drug reactions and serum sickness suggest that the former are allergic in nature However drug reactions differ from the classical types of anaphylactic and tuberculin hypersensitivity in that (1) circulating antibodies and skin sensitivity can rarely be demonstrated (2) the interval between the first exposure to a drug and the appearance of a reaction is inconstant and (3) the manifestations of the reaction are unpredictable varying not only in different individuals but also with the particular drug involved It is especially difficult to explain why a single drug may produce fever and rash in one individual hepatitis in another or a depression of myelopoiesis in a third and why different drugs vary with respect to the frequency with which they induce one or another manifestation of hypersensitivity

The *morphologic changes* in the liver vary from case to case but in general fall into one of two patterns In the first which is more common there are irregularly distributed focal areas of parenchymal degeneration and necrosis and an intense portal inflammatory reaction with little or no fatty infiltration Occasionally the lesions are difficult to distinguish from those of acute viral hepatitis and rarely they are sufficiently extensive to produce the picture of subacute hepatic necrosis As a rule the lesions regress when the offending agent is withdrawn but occasionally the hypersensitivity reaction appears to trigger a progressive inflammatory process which may result in cirrhosis

The second type seen following reactions to chlorpromazine and the arsphenamines and less commonly after the sulfonamides neocinchophen and thiouracil is characterized by marked intralobular bile stasis and an intense predominantly mononuclear and eosinophilic inflammatory reaction in the portal triads In contrast the parenchymal cells show little or no change These features bear a striking resemblance to those of cholangiolitic hepatitis and extrahepatic biliary obstruction Occasionally the disease runs a long course despite the cessation of drug administration and rarely a type of biliary cirrhosis develops

The *clinical and laboratory features* of the more common type of drug hepatitis resemble those of acute viral hepatitis However the signs of liver disease are often preceded or accompanied by other manifestations of hypersensitivity such as fever rash arthralgia lymphadenopathy and signs of renal or hematopoietic injury Also there is a tendency for the serum alkaline phosphatase to be higher and the cephalin cholesterol and thymol turbidity reactions to be weaker than in viral hepatitis

In the type of hepatitis produced by drugs like chlorpromazine symptoms suggesting an extrahepatic biliary obstruction appear following a brief episode of fever and other constitutional symptoms The latter may or may not be associated with more distinctive signs of hypersensitivity Often the icterus is accompanied by dark urine and clay colored stools and pruritus may be a prominent feature The serum bilirubin and alkaline phosphatase levels tend to be as high as in obstructive jaundice while the cephalin cholesterol flocculation and thymol turbidity reactions are normal

Usually the hepatitis subsides within a few weeks following withdrawal of the offending drug However it may run a more chronic course occasionally terminating in a form of biliary cirrhosis (p 1506)

The *diagnosis* may be exceedingly difficult if there are no other manifestations of hypersensitivity A history of drug ingestion is helpful but obviously it does not exclude the possibility of an unrelated viral hepatitis or biliary obstruction Eosinophilia is an inconstant finding but when present favors a drug reaction Unfortunately even a liver biopsy may be inconclusive so that exploratory laparotomy may be indicated in cases with prolonged jaundice of doubtful etiology

In patients receiving a number of drugs it may be difficult to determine which is responsible for

the reaction Even a clinical trial following recovery may be misleading since multiple sensitivities may develop as a result of a reaction to a single drug Moreover it is unwise to carry out such tests since severe and even fatal reactions may ensue

The principles of *treatment* are the same as for toxipathic hepatitis In addition ACTH and cortisone may be useful adjuvants in severe illnesses Obviously at the first sign of a reaction the offending drug should be withdrawn However this may fail to abort the reaction Occasionally spontaneous or induced desensitization permits resumption of drug therapy following recovery However unless *the drug is urgently needed it is unwise to use it* again

Hepatitis Associated With Systemic Infections

Bacterial Infections Many systemic infections are accompanied by minor functional and structural changes in the liver that have little clinical significance Occasionally however severe bacterial infections give rise to sufficiently extensive hepatic lesions to produce jaundice and in rare instances may be responsible for progressive hepatocellular failure

Although the liver plays an important role in removing bacteria that gain access to the blood the parenchyma seldom becomes infected in the process More often the signs of hepatic damage which accompany systemic infections are due to circulating toxins or to the effects of such nonspecific factors as fever anemia hypoxia and malnutrition Some of the infectious agents involved are known to have in vitro hemolytic properties However except in the case of *Clostridium welchii* sepsis it is doubtful that hemolysis plays a significant role in the production of jaundice

Almost any severe bacterial infection may give rise to toxic hepatitis but the organisms implicated most frequently include pneumococci streptococci gonococci *Escherichia coli* and the *Salmonella* group While bacteremia is often present in such infections it does not appear to be essential for the development of toxic hepatitis as for example in pneumococcal pneumonia scarlet fever typhoid fever and food poisoning with *Salmonella typhimurium* and *Salmonella enteritidis*

The *pathologic changes* in the liver are nonspecific They may include focal areas of hepatocellular degeneration and necrosis signs of regeneration and an inflammatory reaction in the portal triads

The *clinical and laboratory features* resemble those in toxipathic hepatitis As a rule the signs of hepatic damage subside promptly as the underlying infection is brought under control In most cases the hepatitis does not appear to add materially to the severity of the illness However in rare in-stances severe hepatocellular failure may be contributory to a fatal outcome

Not all forms of jaundice accompanying severe infections can be attributed to toxic hepatitis In *E coli* bacteremia and in typhoid and paratyphoid fever it may be due to a complicating acute cholangitis while in *Cl welchii* sepsis it is usually the result of acute intravascular hemolysis and the destructive action of the invading organisms on the hepatic parenchyma Occasionally the jaundice that occurs in *Salmonella* and *Shigella* infections is due to a coincidental acute viral hepatitis Double infections of this type are not rare during concurrent epidemics of the two diseases Finally the possibility of a drug induced hepatitis must not be forgotten in evaluating the pathogenesis of any hepatitis that occurs during an infection.

Infectious Mononucleosis On the basis of histologic studies and tests of hepatic function it would appear that the liver almost always participates in the generalized inflammatory reaction of the reticuloendothelial system that characterizes infectious mononucleosis However overt clinical manifestations of hepatic involvement are relatively uncommon jaundice occurring in from 5 to 10 per cent of cases and hepatomegaly only slightly more frequently

The outstanding finding in the liver is an intense inflammatory reaction involving the sinusoids and portal triads The exudate is largely mononuclear consisting of atypical lymphocytes monocytes plasma cells and swollen proliferating Kupffer cells Occasionally the latter are arrayed in rosettes forming small granulomatous nodules in the sinusoids A few scattered parenchymal cells may exhibit early degenerative changes but hepatocellular necrosis is distinctly unusual despite the fact that the parenchymal cells often show evidence of active regeneration In jaundiced cases the canaliculi not infrequently contain bile thrombi Except for swelling and cellular infiltration, the portal triads are not altered

Abnormalities of "liver function" are demonstrable in most cases those depending on alterations in the serum protein pattern such as the cephalin cholesterol flocculation and thymol turbidity reactions predominating Since the latter can seldom be correlated with evidence of hepatocellular injury histologically and since they often persist long after clinical recovery it is highly probable that they are in part at least due to nonspecific changes in serum protein related to the underlying infection Characteristically the serum albumin level falls while the gamma globulin concentration rises Occasionally there is a less pronounced increase in alpha 1 and beta globulin Strongly positive cephalin cholesterol flocculation reactions and increased levels of thymol turbidity are seen in at least 80

other forms of tuberculosis however signs of liver disease are unusual except for slight hepatomegaly and nonspecific minor alterations in function which may be unrelated to the presence of hepatic granulomas

Three rare forms of hepatic tuberculosis are characterized by marked enlargement and tenderness of the liver chills and fever jaundice and a rapid downhill course They are (1) pylephlebogenous tuberculosis in which there is massive dissemination of tubercle bacilli to the liver by way of the portal vein from an intraabdominal focus (2) hepatic tuberculomas which are large caseating masses or abscesses of tuberculous origin and (3) tuberculous cholangitis or tubular tuberculosis of the liver a condition which arises as a result of rupture of a caseating tuberculoma or abscess into the biliary tract and subsequent spread of the infection along its course

Brucellosis Granulomas can be demonstrated in the liver in a high proportion of patients with active *Brucella abortus* infections they are relatively uncommon in *Brucella suis* and *Brucella melitensis* infections

The lesions seldom give rise to clinical manifestations although hepatomegaly is common Several instances of jaundice have been reported but they are rare Hepatic function is little impaired and may be normal even in the presence of granulomas

Occasionally cirrhosis is a late complication of brucellosis It is still not certain whether this is a sequel to healing of granulomas or the consequence of associated malnutrition

Cirrhosis

Any diffuse fibrosis that destroys the normal lobular architecture of the liver may be properly classified as a form of cirrhosis Characteristically the parenchymal cells lying between the connective tissue septums are arranged in islands that differ from normal lobules not only in size and shape but also in their lack of normally oriented central veins and portal triads They may represent segments of lobules isolated by encircling fibrous bands or nodules of regenerating parenchyma and may vary in size from less than a millimeter to several centimeters in diameter Other features seen in many but not all cases of cirrhosis include degeneration atrophy and necrosis of parenchymal cells an inflammatory reaction usually most marked in the periportal areas proliferation of the small perilobular bile ducts and alterations in the intrahepatic vasculature characterized by compression distortion and reduction in the size of either the portal or hepatic venous bed and the occurrence of abnormal shunts between the major vascular components of the lobules In addition, there may be a number of changes related to the specific effects of certain etiologic factors The deposition of iron containing pigment in hemochromatosis may be cited as an example

Although there are well-defined differences in the pathogenesis of the several known types of cirrhosis the basic fibrotic process in all appears to be the consequence of hepatocellular necrosis or atrophy resulting in collapse and condensation of the normal supporting reticulum followed by deposition of collagen It is doubtful that the apparent proliferation of connective tissue from periportal and pericentral foci is the primary cause of parenchymal replacement although it may contribute to the process by compressing adjacent hepatic cells or by reducing their blood supply

As the cirrhotic process advances signs of hepatocellular failure and portal hypertension appear owing to progressive degeneration and obliteration of the parenchyma and to obstruction to the outflow of portal blood However cirrhosis is not always progressive Indeed, the disease may remain asymptomatic or may regress once overt manifestations have appeared Although experimental evidence suggests that even fibrosis may diminish under certain conditions the improvement that occurs in man appears to be due to the recovery of injured liver cells the replacement of lost cells by active regeneration and the resolution of inflammatory exudates

Occasionally the etiology of the cirrhotic process may be inferred from the morphologic changes in the liver but more often the differentiation among the several known types of cirrhosis depends in part at least on collateral historical and clinical evidence This is not surprising considering the limited number of ways in which the liver can react to diverse types of injury

The forms of cirrhosis that are recognized clinically include the following (1) Laennec s (2) postnecrotic (3) biliary (4) cardiac (5) hemochromatosis (6) hepatolenticular degeneration (Wilson s disease) (7) cirrhosis due to schistosomiasis and (8) rarer types

Laennec s Cirrhosis

Definition Laennec s cirrhosis by far the most common type encountered is characterized by a fine diffuse fibrosis of the liver often accompanied by fatty infiltration and degeneration of the parenchyma Malnutrition and chronic alcoholism are the major factors involved in its pathogenesis but in some instances the etiology is obscure Occasionally the hepatitis virus and certain poisons give rise to lesions which in their late stages closely resemble those of Laennec s cirrhosis However because of the manner in which they develop such lesions are usually classified as forms of postnecrotic cirrhosis

per cent of cases Bromsulphalein retention increases in serum alkaline phosphatase and urine urobilinogen and decreases in prothrombin and serum cholesterol esters are less common findings Hyperbilirubinemia and bilirubinuria occur in from 10 to 30 per cent of cases

In general the histologic changes and alterations in hepatic function parallel the severity of the underlying infection What role the former play in producing clinical manifestations is difficult to assess However it is doubtful that the minor changes in the liver that occur in most anicteric cases contribute significantly to the symptomatology or clinical course of the disease When the hepatic lesions are more extensive and particularly when jaundice occurs the symptoms may resemble those of acute viral hepatitis suggesting that they are of hepatic origin

The jaundice that occurs in infectious mononucleosis tends to be mild and usually clears up within a few weeks Its appearance may precede or coincide with the onset of lymphadenopathy Occasionally the lymph nodes fail to enlarge in which case the etiology of the fever and jaundice may be more difficult to identify Often the jaundice is accompanied by slight tenderness and enlargement of the liver and by splenomegaly The other clinical manifestations of infectious mononucleosis are described elsewhere (p 1151)

The biochemical changes suggesting hepatic involvement usually return to normal by the end of the second month but in occasional instances they persist for many months However there is no convincing evidence that infectious mononucleosis gives rise to cirrhosis or to any other form of chronic hepatic disease

In the presence of jaundice it may be difficult to differentiate infectious mononucleosis from acute viral hepatitis The occurrence of sore throat significant lymphadenopathy or chills favors the former Atypical lymphocytes may appear in the blood in both diseases but seldom exceed 10 per cent of the total leukocyte count in acute viral hepatitis In the last analysis the diagnosis must be established serologically (p 1153)

The hepatic lesions of infectious mononucleosis require no special treatment There is no convincing evidence to indicate that dietary measures shorten the course of the disease or have any effect on the symptoms

Leptospirosis See p 1014

Granulomatous Hepatitis

The liver often participates in generalized granulomatous reactions of such varied etiology as sarcoidosis tuberculosis brucellosis certain mycoses and berylliosis The lesions which consist of discrete collections of epithelioid and giant cells apparently derived from the reticuloendothelium to displace adjacent hepatic cells as they exp However they usually remain quite small so the loss of parenchyma is minimal even wher lesions are numerous Rarely they coalesce to large lesions in which case they may produce and symptoms of liver disease

As a rule it is difficult to distinguish betw the hepatic granulomas of different diseases morphologic basis alone Central necrosis is common in tuberculosis brucellosis and my infection than in sarcoidosis and berylliosis b is an inconstant finding and caseation whic such a common feature in tuberculous lesions where in the body is rare in the liver Occas ally by means of special stains or cultural meth it is possible to demonstrate the underlying etiol agent

Sarcoidosis In approximately 70 per cen patients with sarcoidosis it is possible to den strate the presence of hepatic granulomas by m of needle biopsy Since this approaches the i dence found at autopsy it may be inferred usually the lesions are numerous and unifor distributed Nevertheless they seldom give ris symptoms although mild degrees of hepatome and minor alterations of function are common high serum alkaline phosphatase level seen in disease appears to be more closely related to presence of hepatic granulomas than to the currence of lesions in bone Rarely the granulo tous reaction and the fibrosis that follows are extensive that overt signs of liver disease app These signs may include marked hepatomeg jaundice ascites splenomegaly and bleed esophageal varices and they may be mistaken evidence of other types of cirrhosis especially there are no extrahepatic manifestations of coidosis As a rule the diagnosis depends on l biopsy although it may be suspected when th are other signs of the disease

Tuberculosis Needle biopsy studies indicate t hepatic granulomas can be demonstrated in m patients with acute miliary tuberculosis and in proximately half of those with other forms of disease Presumably the lesions are indicative o hematogenous spread of the infection but si acid fast organisms can seldom be demonstrat the question arises whether the granulomas m not represent a nonspecific response to the infecti In addition to the granulomas fatty infiltrati portal fibrosis and less commonly Laennec's c rhosis may be found These appear to be relat to the malnutrition which may accompany this d ease

Occasionally the number of hepatic granulom in acute miliary tuberculosis is so great that signi cant hepatomegaly and jaundice develop In mo

develop cirrhosis than undernourished invalids whose diets are likely to be deficient in both protein and calories

It should be noted that while chronic alcoholism may be an important factor in the pathogenesis of cirrhosis only a small proportion of chronic users of alcohol actually develop cirrhosis No doubt differences in dietary habits play a role but marked differences in individual susceptibility appear to be an equally important factor This has been confirmed in animal experiments

Pathology In the incipient stage of the disease the liver is enlarged and pale owing to the presence of large fat globules in the parenchymal cells As these become more numerous stellate shaped areas of fibrosis appear in the portal areas and to a lesser extent around the central veins Later thin connective tissue septums join the portal triads and traverse the lobules breaking them up into islands of cells which tend to proliferate forming small nodules or pseudolobules As the disease progresses the fibrous bands become thicker and more numerous are infiltrated by mononuclear cells and incorporate an increasing number of blood vessels and regenerating perilobular bile ducts At the same time foci of degeneration and necrosis infiltrated with mononuclear and polymorphonuclear cells appear in the parenchyma while the amount of fatty infiltration tends to decline Often the cytoplasm of the hepatic cells contains highly characteristic eosinophilic droplets and club shaped masses of hyalinelike material known as *Mallory bodies* These are especially common when chronic alcoholism is an etiologic factor and may be very numerous when the disease is severe In jaundiced patients the canaliculi may contain plugs of inspissated bile and occasionally there is bile staining of the parenchymal and Kupffer cells

Late in the disease the liver is firm and finely nodular or granular but occasionally it is coarsely nodular with broad intervening connective tissue septums very much as in postnecrotic cirrhosis Whether this represents a morphologic variant of Laennec s cirrhosis dependent on a more acute patchy type of necrosis with more active regeneration than in the usual case or whether it is the sequela of an unrecognized intercurrent infection with the hepatitis virus is still uncertain The size of the liver is variable being small in some cases and large in others

As previously indicated the fibrosis in Laennec s cirrhosis appears to be the consequence of hepatocellular necrosis and collapse of normal supporting reticulum Whether fatty infiltration plays an important role in this process is still uncertain, particularly since fatty livers do not necessarily become fibrotic In animal experiments it has been shown that large fat globules in adjacent cells tend to coalesce forming large cysts and that as the fat is reabsorbed the reticulum fibers derived from the original cells collapse to form a network of fine septums which ultimately undergo collagenization. However it is doubtful that this is the only way in which fibrosis can develop

In the florid form of Laennec s cirrhosis which occurs exclusively in alcoholic addicts the predominant findings are extensive and there is severe hepatocellular degeneration and necrosis with numerous Mallory bodies and infiltrating polymorphonuclear cells Fatty infiltration and fibrosis vary in extent and may be negligible

Clinical Features Usually the onset is insidious with nonspecific complaints including anorexia weakness and unusual fatigability that relate both to early hepatic dysfunction and the accompanying underlying malnutrition and chronic alcoholism Although weight loss is common late in the disease it may be absent in its early phases This relates to the fact that while the alcoholic addict is malnourished in the sense that the quality of his diet is poor he frequently obtains a sufficient number of calories in the form of alcohol to maintain or even gain weight Similarly the natives of tropical areas who develop nutritional cirrhosis often show no evidence of wasting since their caloric intake in the form of carbohydrate tends to be high despite a deficiency of protein

As the disease advances signs of frank hepatocellular failure and portal hypertension appear The former include jaundice ascites edema pleural effusion, alterations in serum electrolytes spider nevi palmar erythema gynecomastia testicular atrophy impotence loss of axillary and pubic hair and a bleeding tendency (pp 146 150) the latter splenomegaly esophageal varices with or without massive bleeding and a visible venous collateral circulation over the abdomen (p 149) Usually the symptoms of hepatocellular failure dominate the clinical picture but not infrequently the signs of portal hypertension can be demonstrated even before symptoms appear and occasionally massive bleeding from esophageal varices is the initial manifestation

Low grade fever nausea vomiting diarrhea and abdominal pain are common complaints in the stage of advanced hepatic failure As indicated previously the pathogenesis of these symptoms is uncertain Usually the pain is mild and aching in character but occasionally and especially in the florid form of the disease it may be severe and cramping and may be mistaken for biliary colic or a sign of ruptured peptic ulcer Hepatomegaly is an inconstant but fairly frequent finding When palpable the liver usually is very firm occasionally it is

Laennec's cirrhosis is known also as *alcoholic fatty portal* or *atrophic* cirrhosis These terms would appear to be inappropriate since (1) alcohol is not always an etiologic factor (2) fatty infiltration is not demonstrable in all cases (3) the fibrous septums radiate not only from the portal triads but also from the central veins and (4) the liver may be either large or small depending on the relative degrees of fatty infiltration fibrosis and hepatocellular necrosis and regeneration

Etiology Laennec's cirrhosis is thought to be the consequence of a specific type of malnutrition usually related to chronic alcoholism and/or faulty dietary habits In this country and in many parts of Europe chronic alcoholism is a major etiologic factor in approximately 75 per cent of cases but in England and in other parts of the world it plays a relatively unimportant role A faulty diet almost certainly accounts for the prevalence of the disease among nonalcoholics in certain tropical and subtropical areas but does not appear to be a significant factor in the pathogenesis of cirrhosis among nonalcoholics in the Temperate Zone On the basis of indirect evidence it has been suggested that viral hepatitis may be of etiologic importance in such cases To be sure the hepatitis virus is capable of producing a finely nodular cirrhosis but the resulting lesion differs from that in the usual form of Laennec's cirrhosis not only in its mode of development but also in many of its histologic features and hence should be classified as postnecrotic along with other forms of posthepatitic cirrhosis

Occasionally Laennec's cirrhosis is a complication of other diseases In a few instances the lesion appears to be the consequence of malnutrition due either to an absorptive defect as in pancreatic insufficiency or to a poor dietary intake as in ulcerative colitis chronic malaria and chronic dysentery but in other conditions such as diabetes mellitus galactosemia and thyrotoxicosis the pathogenesis of the cirrhosis is obscure

It is generally agreed that alcohol is not a hepatotoxin and that its effects on the liver probably are secondary to an associated nutritional disturbance However the nature of the deficiency and the precise mechanism responsible for the development of cirrhosis are still uncertain According to one widely held theory excessive drinking merely reduces food intake and thus leads to a deficiency of lipotropic substances including choline its precursor methionine vitamin B_1 folic acid and possibly some of the other amino acids like threonine lysine and tryptophan that affect the lipid content of the liver As a result the liver becomes fatty and ultimately undergoes fibrosis It is believed that the accumulation of fat under these conditions is due to a reduced rate of fatty acid oxidation in the liver but it is not known whether the fibrosis is the direct consequence of fatty infiltration or an independent sequela of the lipotropic deficiency *In support of* the lipotrope theory it has been shown that (1) diets rich in protein and hence high in lipotropic activity are effective in the treatment of Laennec's cirrhosis (2) it is possible to produce a similar lesion in animals by reducing the intake of protein and other lipotropic substances and (3) the diet in tropical and subtropical areas where Laennec's cirrhosis is common is low in protein content However it has been found that in animals on low protein diets and in children with kwashiorkor a form of malignant malnutrition seen in the tropics supplements of protein are far more effective in reversing the associated hepatic lesions than equivalent amounts of choline or methionine suggesting that the injurious effects of low protein diets on the liver are due to more than a simple deficiency in lipotropic activity Moreover since the hepatic lesions of uncomplicated protein deficiency show few of the characteristic degenerative and inflammatory changes seen in Laennec's cirrhosis the question arises whether nondietary factors may not be involved in their pathogenesis In particular the role of infection merits further investigation since intercurrent bacterial infections so often appear to accelerate the progress of the lesions in Laennec's cirrhosis Moreover the unusual incidence of carriers of the hepatitis virus among alcoholic addicts with cirrhosis suggests the possibility that activation of the virus may be a factor in the evolution of the lesion in some instances

A number of clinical observations cast doubt on the concept that the effects of chronic alcoholism on the liver are due solely to a reduction in food consumption In particular it may be pointed out that alcoholic addicts occasionally develop Laennec's cirrhosis despite an apparently adequate dietary intake and that simple undernutrition such as occurs in many chronic illnesses seldom gives rise to cirrhosis Recent animal experiments have shed some light on this problem They have shown that while the ingestion of alcohol leads to a decrease in food consumption apparently in response to the homeostatic mechanism controlling the caloric intake it also raises the requirement for lipotropic substances first by increasing the total caloric intake and second by some other as yet unidentified mechanism not dependent on the calorigenic activity of alcohol These observations may explain why apparently adequate diets occasionally fail to protect against the development of cirrhosis in individuals who consume a large number of alcohol calories and why the natives of tropical and subtropical areas whose diets are low in protein but high in carbohydrate calories are more likely to

that more effective methods of combating infection and controlling hemorrhage and more stringent control over the patient s drinking habits and phys ical activity have contributed to the results It should be noted in this connection that intercurrent infection and hemorrhage still account for almost half the deaths that occur which emphasizes the need for meticulous care and close supervision of the cirrhotic patient

Treatment A nutritious diet strict prohibition of alcohol judicious regulation of salt and water bal ance prompt control of hemorrhage and replace ment of lost blood a prompt and vigorous attack on all intercurrent infections and provision for ade quate rest are the mainstays of treatment in Laen nec s cirrhosis

A palatable *diet* containing from 80 to 120 Gm protein and 2500 to 3000 cal depending on the patient s size and degree of malnutrition appears to be adequate for the needs of the liver and the re plenishment of depleted tissue stores There is no convincing evidence that a larger intake of protein is more effective as far as the recovery of the liver is concerned but it may restore the wasted tissues more rapidly However it usually is difficult to get sick patients to consume such large diets and there is the potential hazard of precipitating hepatic coma in those with extensive portacaval shunting There is no need to restrict fat so that the patient s per sonal preferences and tolerance may be used as a guide in adjusting the ratio of fat to carbohydrate calories

Vitamin supplements are indicated in patients with overt signs of deficiency and in those who will not or cannot eat but they are an unnecessary ex pense to patients who are consuming a well bal anced diet Similarly *choline* and *methionine* sup- plements may be helpful in individuals with fatty livers who are poor eaters but they are of no value if the protein intake is adequate Moreover methio- nine may be toxic in some individuals (p 152) *Intravenous liver extract* and *vitamin* B_1 are al leged to stimulate the appetite but the evidence for this is not convincing *ACTH* and *cortisone* are more effective in stimulating the appetite and create a sense of well being but the frequency of unde sirable side effects such as increased fluid reten tion hemorrhage from esophageal varices and un recognized peptic ulcer and portal vein thrombosis contraindicates their use except under special cir cumstances *Testosterone propionate* has been rec ommended on the grounds that it facilitates protein storage and increases the patient s strength How ever the minimal benefits to be derived do not appear to justify the cost and inconvenience of such therapy

Salt restriction is the simplest and one of the most effective means of managing fluid retention and should be the first employed when ascites edema and hydrothorax appear (p 148) Often limitation of the sodium intake to 500 mg (22 mEq) a day will suffice but it may be necessary to reduce the intake to 200 mg (10 mEq) to promote a diuresis Unfortunately restricting salt makes it difficult to prepare diets rich in protein. However this can be achieved by the use of salt poor deriva tives of milk protein like Lanolac and salt free bread If salt restriction is ineffective in relieving edema and ascites *mercurial diuretics* and *am monium chloride* may be used provided the po- tential hazards of salt depletion (p 149) and am monia intoxication (p 152) are kept in mind Intravenous infusions of *concentrated human al bumin* may be helpful in producing a diuresis when other measures have failed and occasionally for reasons that are not clear they appear to improve the general clinical status of severely ill patients Unfortunately they may produce bleeding from esophageal varices or may precipitate pulmonary edema if given too rapidly so that they must be used with caution and only when other therapeutic measures have been ineffective *Paracentesis* and *thoracentesis* are indicated whenever the amount of fluid accumulated is sufficiently great to produce symptoms Their number should be kept to a mini mum since they waste protein and subject the pa tient to the hazards of the salt depletion syndrome Application of a tight abdominal binder and restric tion of water for a period of 24 hr following para centesis will do much to prevent the latter If this fails a slow infusion of albumin to maintain the blood volume may be more effective Obviously sodium administration is indicated once the salt depletion syndrome has appeared

The occurrence of massive bleeding from esoph ageal varices calls for immediate *balloon tamponade* of the esophagus and *transfusion* of whole blood In transfusing blood an attempt should be made to replace the estimated loss and to maintain the hematocrit at a normal level The triple lumen double balloon tube described by Sengstaken and Blakemore appears to be the most effective type of tampon available The inflated lower balloon anchors the tube at the cardia, while the upper one compresses the bleeding varices Two of the lumens are used for inflating the balloons while the third is used for aspirating gastric contents and for feeding Frequent checks on the pressures in both balloons are essential since many failures are at tributable to their improper inflation and place ment The tube is deflated 72 hr after blood can no longer be aspirated from the stomach, but is left in place for another 24 hr to detect any recurrence of bleeding It may be necessary to reinflate the balloons several times before a firm clot is formed There is the danger of course that tamponade for

slightly tender The nodules on its surface can rarely be felt

Impending and overt hepatic coma usually are *signs of terminal hepatocellular failure* However they may be indicative of portacaval shunting of nitrogenous substances from the intestine as a consequence of massive hemorrhage or the ingestion of excessive amounts of protein (p 152) and they may be reversible

In the florid form of the disease the onset tends *to be more acute and the* progression of symptoms *more rapid and less responsive to treatment* Often nausea vomiting abdominal pain high fever and marked leukocytosis are prominent features

Usually hepatic decompensation is the consequence of progressive hepatocellular failure resulting from prolonged malnutrition and overindulgence in alcohol However it may be precipitated acutely by *massive gastrointestinal* bleeding intercurrent *infection* surgical trauma or the development of a complicating hepatoma

The principal complications of Laennec s cirrhosis include bleeding from esophageal varices hepatoma portal vein thrombosis and intercurrent infection Bacteremia apparently arising in the tributaries of the portal vein is an occasional terminal event Peptic ulcer and acute pancreatitis are *common complications* but appear to be more *closely* related to the accompanying chronic alcoholism than to the cirrhosis

Laboratory Features The results of *liver function tests* point to hepatocellular damage Bromsulphalein retention is an almost invariable finding even when other tests are negative The serum albumin level falls progressively as the disease advances while the serum globulin and especially the *gamma fraction* tends to rise The direct and total serum bilirubin concentrations may be normal but often are increased to a variable degree The cephalin cholesterol flocculation test usually is positive but thymol turbidity often remains normal The serum alkaline phosphatase concentration tends to increase slightly but occasionally it rises to the levels seen in obstructive jaundice In most cases there is no change in the total serum cholesterol but often the unesterified fraction is increased especially when jaundice is present A subnormal cholesterol concentration usually signifies advanced hepatocellular failure and is a bad prognostic sign All these changes tend to revert to normal under treatment although Bromsulphalein retention usually persists

Moderate *anemia* is a common finding Usually it is normocytic or slightly macrocytic in character and often it is accompanied by a hyperactive normoblastic bone marrow mild reticulocytosis and a decrease in the red cell survival time features suggesting a hemolytic basis possibly related to overactivity of the spleen although other factors cannot be excluded As might be expected *treatment with iron liver extract and vitamin B_1 is seldom* effective A few instances of frank hemolytic anemia with a positive Coombs test result have been reported These have been attributed to hypersplenism" Occasionally the anemia is microcytic and hypochromic as a result of chronic blood loss from esophageal varices or hemorrhoids Rarely the anemia is megaloblastic and *responds to vitamin* B_1 or citrovorum factor suggesting a nutritional basis

Slight *leukopenia* and *thrombocytopenia* are common and probably represent manifestations of "hypersplenism As previously mentioned *leukocytosis* is the rule in florid cirrhosis the count often ranging between 20 000 and 50 000 per cubic millimeter In other cases lesser degrees of leukocytosis may occur when there is active hepatocellular necrosis and degeneration

Diagnosis With a history of chronic alcoholism or malnutrition a firm liver and signs of hepatocellular failure and portal hypertension the diagnosis of Laennec s cirrhosis presents no problem However in the absence of any one or several of these features the differentiation from other diseases may be difficult The particular disorders to be considered in any given case will depend on the presenting manifestations they include such diverse conditions as other forms of cirrhosis hepatitis intrahepatic malignancy portal and hepatic vein obstruction congestive heart failure constrictive pericarditis various infiltrative and granulomatous diseases that involve the liver and spleen and bleeding peptic ulcer Usually a thorough clinical investigation including tests of liver function will serve to distinguish among these disorders but in doubtful cases a biopsy of the liver may be required

Prognosis There is no doubt that the modern all out therapeutic attack on Laennec s cirrhosis is effective in restoring many patients to good health provided vigorous treatment is begun at an early stage of the disease This is reflected in the increased life expectancy reported by several investigators However the mortality rate is still distressingly high in patients with advanced hepatocellular failure or bleeding esophageal varices Thus of patients with ascites approximately 35 per cent are dead in 1 year 50 per cent in 2 years and 70 per cent in 5 years Even more alarming statistics may be cited for the group with massive bleeding but there is some hope that *recently* developed surgical techniques for controlling portal hypertension may reduce these figures

The improvement in the outlook for the cirrhotic patient usually is credited to the introduction of modern dietary therapy However while this represents an important advance there is little doubt

acteristic picture of large nodules separated by broad bands of stromal collapse and fibrosis The size of the nodules and the breadth of the connective tissue septums vary depending on the distribution and extent of the original necrosis In typical cases broad zones of necrosis traverse the parenchyma subdividing it into large lobular aggregates which tend to proliferate thereby increasing the size and distorting the architecture of their constituent lobules Occasionally the necrosis is so extensive that an entire lobe usually the left is destroyed leaving nothing but stroma A finely nodular or granular cirrhosis may be produced if the zones of necrosis and collapse are diffusely distributed in a fine pattern This type may be difficult to distinguish from Laennec's cirrhosis unless the process is active and some of the characteristic histologic features of the underlying acute disease are still evident

Postnecrotic cirrhosis is known by a variety of other names including *postnecrotic scarring toxic cirrhosis posthepatitic cirrhosis coarsely nodular cirrhosis healed yellow atrophy* and *Marchand's multiple nodular hyperplasia*

Etiology Most instances of postnecrotic cirrhosis represent the sequelae of subacute hepatic necrosis due to the hepatitis virus (p 1487) In some the manifestations of cirrhosis follow so closely on the heels of a typical attack of acute viral hepatitis that there can be little doubt about the etiology but in others the onset is insidious so that the viral origin of the lesion must be inferred from either the character of the histologic changes in the liver or a history suggestive of infection in the past Less commonly postnecrotic cirrhosis is the consequence of subacute hepatic necrosis due to poisoning with carbon tetrachloride chloroform the chlorinated naphthalenes and diphenyls tetrachlorethane TNT or mushrooms (*A phalloides*) or to the administration of drugs like cinchophen

Late in the disease there may be none of the earmarks of the acute necrosis responsible for the fibrosis so that the viral or toxic origin of the lesion may be difficult to establish especially if the nodules are of the small variety Many instances of cirrhosis seen among nonalcoholics fall into this group Occasionally a coarsely nodular cirrhosis resembling the postnecrotic variety is seen in the de Toni Fanconi syndrome a congenital renal tubular defect associated with hypophosphatemia rickets glycosuria and aminoaciduria and in hyperthyroidism The pathogenesis of the cirrhosis in these cases is obscure

Animals fed a diet low in cystine methionine tocopherol and an agent found in casein develop a type of subacute or massive hepatic necrosis which on healing gives rise to necrotic cirrhosis Accordingly it has been proposed that the hepatitis virus poisons and drugs may induce a deficiency of essential sulfhydryl groups in the liver by interfering with the intrahepatic circulation by diverting sulfhydryl groups to other purposes or by increasing the demands for sulfhydryl groups and thus produce subacute hepatic necrosis and postnecrotic cirrhosis However there is no convincing evidence that any of these mechanisms is involved in the pathogenesis of postnecrotic cirrhosis in man.

Pathology The evolution of the lesion in the viral type of postnecrotic cirrhosis has been described elsewhere (p 1487) Except for the occurrence of fatty infiltration early in the course of the disease the zonal distribution of the necrosis and the character of the inflammatory reaction which tends to be less extensive but more polymorphonuclear in type the toxic form of postnecrotic cirrhosis develops in the same manner

The features that distinguish the posthepatitic type from Laennec's cirrhosis include the following (1) the nodules usually are larger vary more in size and shape and often contain several intact but abnormally oriented central veins and portal triads (2) the septums tend to be broader show a more intensive mononuclear inflammatory reaction and contain many more blood vessels regenerating bile ducts and collapsed and thickened reticulum fibers but fewer collagen fibers (3) the parenchyma shows a more active type of regeneration with the appearance of bizarrely shaped multinucleated cells and often exhibits eosinophilic Councilman like hyaline bodies (p 1487) scattered foci of necrosis and degeneration and a mononuclear exudate (4) often the veins show an inflammatory reaction in their walls and (5) fatty infiltration and Mallory bodies (p 1501) are rare

Clinical Features Often the overt manifestations of cirrhosis appear insidiously (1) during convalescence from an otherwise uncomplicated and sometimes very mild attack of acute viral or toxic hepatitis (2) after one or more relapses following an attack of acute hepatitis (3) following a vague anicteric illness presumably due to the hepatitis virus or (4) in an individual in apparent good health who may or may not give a history of previous hepatitis Occasionally the onset is acute and severe with signs of subacute hepatic necrosis (p 1490) following which progression to the stage of fibrosis may be remarkably rapid

The clinical features are very much like those of Laennec's cirrhosis (p 1501) except that (1) jaundice appears at an earlier phase and is more likely to be persistent or to recur at intervals (2) abdominal pain and gastrointestinal symptoms are more frequent and tend to be more severe (3) purpura epistaxis and other hemorrhagic phenomena are more common, (4) the liver tends to be smaller and is more often nodular on palpation (5) once

more than 5 or 6 days may produce esophageal ulceration However this risk must be accepted since uncontrolled hemorrhage is likely to be fatal Another hazard of tamponade to be guarded against is asphyxia due to displacement of the balloon up into the pharynx Usually this can be avoided by fixing the tube at the external nares by means of tape rather than by applying traction with a suspended weight and by using restraints on the patient s hands if he is uncooperative and shows any tendency to tug at the tube If the tube slips and respiratory distress ensues the tube should be cut with a pair of scissors and pulled out at once Attempts to deflate both balloons in the usual way may be disastrous Since the regurgitation of gastric juice may be a factor in the pathogenesis of variceal ulceration and in the prevention of firm clot formation suppression and neutralization of gastric secretion should be attempted by administering Banthine and antacids If the prothrombin time is prolonged large doses of vitamin K are indicated

If hemorrhage from esophageal varices cannot be controlled by conservative measures emergency surgical intervention may become necessary The procedures used include ligation of the hepatic and splenic arteries resection of the cardia and lower esophagus and transthoracic transesophageal suture of the bleeding varices Of these the last has proved to be most effective and least hazardous However the mortality following any of these procedures is high so that none should be undertaken unless it is certain that tamponade and transfusion are ineffective and that the degree of hemorrhage is a threat to life

Once a patient has had a massive hemorrhage from esophageal varices the risk of recurrence is great even after ligation of the vessels and strict adherence to a good medical regime and with each subsequent hemorrhage the chances of survival diminish For that reason there is a growing tendency to advise a surgical attack on either the underlying portal hypertension or the site of varix formation as soon after the first hemorrhage as the patient s condition permits The most impressive results have been obtained with portacaval shunts Recurrences of massive hemorrhage have been infrequent and there is suggestive evidence that longevity has been increased However while it has been shown that 70 per cent of the patients operated upon are alive after 2 years as against only 20 per cent for randomly collected untreated cases little attention has been paid to the fact that the patients selected for surgery have in general been the ones in the best condition and hence the ones most likely to survive multiple hemorrhages if left untreated Nevertheless it cannot be denied that if hemorrhage is prevented the chances of survival for the cirrhotic patient must be improved Unfortunately the postoperative mortality rate following portacaval shunt is still approximately 20 per cent so that the decision whether to operate and when requires fine judgment

Ligation of the hepatic and splenic arteries with splenectomy in the hope of reducing portal pressure is less effective than portacaval shunt and carries an even higher mortality rate *Resection of the cardia and lower esophagus* in an attempt to remove the site of varix formation is used but cannot be recommended since recurrences of varices and hemorrhage are common Recently there has been a renewal of interest in the *injection of esophageal varices* with sclerosing solutions While this is not the treatment of choice since varices are likely to recur it may be useful in patients whose physical condition contraindicates a surgical procedure or in individuals in whom thrombosis of the portal and splenic veins makes portacaval shunt impossible

A period of *bed rest* is strongly recommended for the sick cirrhotic patient Not infrequently it is followed by striking improvement in individuals who have done poorly on an otherwise exemplary regime Similarly in ambulatory patients physical activity should be regulated in an attempt to avoid undue fatigue and exhaustion The basis for the efficacy of rest is not known it may be related to the increase in hepatic blood flow and decrease in over all metabolic activity that accompany inactivity and recumbency

The principles of treatment in hepatic coma are based on current concepts of its pathogenesis (p 152) They include (1) restriction or omission of protein and provision for maintenance of caloric needs in the form of carbohydrate and fat in the comatose patients 2 to 2 5 liters of intravenously administered 15 per cent glucose will suffice (2) correction of any deficits in water blood or electrolytes (3) administration of glutamate either intravenously as the sodium salt in doses of 25 to 50 Gm daily or as the free acid by mouth or by tube at the rate of 2 Gm hourly and (4) broad spectrum antibiotics either orally or by tube Aureomycin Terramycin and neomycin in full therapeutic doses appear to be the most effective If these measures fail it is worth trying large doses of ACTH and cortisone since occasional responses are seen

Postnecrotic Cirrhosis

Definition In contrast to Laennec s cirrhosis which is characterized by the gradual disintegration of cells in small symmetrical foci giving rise to a fine diffuse fibrosis with small nodules postnecrotic cirrhosis is the result of a more acute type of necrosis involving larger areas of parenchyma in a more irregular pattern which produces a char

biliary cirrhosis was called *xanthomatous biliary cirrhosis* in the belief that the xanthomatosis was a manifestation of a primary disturbance in lipid metabolism and that the hepatic lesion was secondary to xanthomatous obstruction of the biliary tract However it is now known that the hypercholesteremia and xanthomatosis in both extra and intrahepatic biliary cirrhosis are manifestations of the underlying liver disease and bear no relationship to familial hypercholesteremia and xanthomatosis and that xanthomatous deposits in the biliary tract play no role in the pathogenesis of cirrhosis It should be emphasized that not all cases of biliary cirrhosis develop xanthomatosis the occurrence of such lesions depending on the magnitude and duration of the serum lipid elevation In general xanthomas occur more frequently in the primary intrahepatic type than in any of the other forms of biliary cirrhosis The longer duration of the disease in the former and the greater delay in the appearance of hepatocellular failure which tends to lower the serum lipids probably account for this difference

Other synonyms sometimes applied to the primary type of intrahepatic biliary cirrhosis include *Hanot s hypertrophic pericholangiolitic cholangiolitic* and *nonobstructive cholangitic biliary cirrhosis*

Pathology Following occlusion of the extrahepatic bile ducts the liver shows a number of characteristic changes which include (1) signs of bile stasis as evidenced by the presence of bile thrombi in the central canaliculi and bile staining of scattered parenchymal and Kupffer cells (2) foci of parenchymal necrosis in the periportal and midzonal areas presumably due to the effects of escaped bile (3) elongation dilatation and proliferation of the interlobular and perilobular bile ducts (4) exudation of polymorphonuclear eosinophilic and mononuclear cells in the portal triads and (5) thickening of the portal triads due to edema exudate duct proliferation and fibrosis If the obstruction is not relieved the portal triads continue to thicken and extend further and further into the parenchyma ultimately bridging adjacent portal triads and giving rise to a perilobular fibrosis At this stage the lobular pattern is still evident but extension of the fibrotic and inflammatory process to the parenchyma ultimately destroys the normal lobular pattern producing the full blown picture of biliary cirrhosis The liver is enlarged finely granular firm and bile stained Large nodules are unusual since the regenerative response of the parenchyma is limited in the face of bile stasis It should be noted that the transition from simple bile stasis to outspoken cirrhosis is a very gradual one and seldom can be recognized clinically except late in the disease

Early in *primary intrahepatic biliary cirrhosis* there is a low grade chronic inflammatory reaction centered about the small perilobular cholangioles This is accompanied by perilobular bile stasis and degenerative changes in the adjacent parenchymal cells As the disease advances fibrosis and inflammation extend into the parenchyma bridging adjacent portal triads and producing the type of perilobular fibrosis seen in early obstructive biliary cirrhosis However the reduplication of the terminal cholangioles is less striking the large interlobular ducts tend to diminish in number and evidence of bile stasis is less prominent Later as the fibrotic process progresses the lobular pattern is obliterated and the picture of cirrhosis emerges At this stage the liver is enlarged bile stained and finely granular

The evolution of the lesion in *cholangiolitic hepatitis and cirrhosis* has been described elsewhere (p 1491)

In *drug induced* biliary cirrhosis the pathogenesis of the lesions closely resembles that of the primary intrahepatic type

It should be emphasized that while it may be possible to distinguish between the lesions in the various forms of biliary cirrhosis early in the course of the disease it is rarely possible to do so by the time the full blown picture of cirrhosis has developed

The pathogenesis of the jaundice in the intrahepatic type of biliary cirrhosis is uncertain Obstruction of the cholangioles by inflammatory exudate and fibrosis and increased cholangiolar permeability with regurgitation of bile are thought to be the principal factors involved but the evidence for this is indirect and inconclusive

Clinical Features In the *primary intrahepatic type* of biliary cirrhosis the onset is insidious with pruritus or less commonly with jaundice As the disease advances pruritus becomes more troublesome jaundice deepens slowly bile appears in the urine and the stools tend to lighten in color Often these signs of biliary "obstruction" fluctuate in intensity Progressive enlargement and induration of the liver occurs and usually is accompanied by significant splenomegaly Many patients develop a striking melanotic pigmentation of the skin and occasionally this is associated with vitiligo Generalized lymphadenopathy is common and occasionally clubbing of the fingers is seen

Some months to years after onset a certain number of patients develop xanthomatosis Usually this can be correlated with a sustained elevation of the serum lipids It has been found that if the total lipids exceed 1 800 mg or if the total cholesterol exceeds 500 mg per 100 ml for a period in excess of 3 months xanthomas may be expected to appear This occurs first as typical xanthelasma of the eyelids and then as flat planus lesions in the

ascites appears the life expectancy is very much shorter and (6) therapy is far less effective

Laboratory Features The results of liver function tests are like those in Laennec s cirrhosis except that (1) the serum globulin level tends to be higher occasionally reaching concentrations of 8 or 9 Gm per 100 ml while the serum albumin level tends to be lower (2) hypocholesteremia is more common and (3) thymol turbidity is increased with greater regularity and higher values are more frequent

Treatment The principles of treatment outlined for Laennec s cirrhosis (p 1503) are equally applicable in this disease Although dietary therapy is less effective as far as recovery of the liver is concerned it is nevertheless important in maintaining the patient s nutritional status during his prolonged illness and in controlling water and salt retention Bed rest is particularly important during the early phase of the disease and during periods of acute progression ACTH and cortisone may be helpful and should be tried in all cases with evidence of active hepatocellular necrosis and inflammation Usually prolonged therapy is indicated so that the dose must be reduced to low maintenance levels as soon as maximum benefit has been achieved in order to minimize undesirable side effects

Biliary Cirrhosis

Definition While it may be difficult to differentiate between biliary and other forms of cirrhosis on morphologic grounds alone especially late in the disease the clinical manifestations and laboratory features of biliary cirrhosis are highly characteristic They include (1) the early appearance and persistence of an obstructive like jaundice with pruritus dark urine and high levels of serum alkaline phosphatase cholesterol and phospholipid (2) marked hepatomegaly (3) a tendency to develop xanthomas of the skin as the serum lipids increase progressively and (4) a relatively benign course for a number of years during which there are few if any clinical or laboratory signs of hepatocellular failure followed ultimately by terminal hepatic decompensation or massive bleeding from esophageal varices

Etiology and Classification There are two major types of biliary cirrhosis one develops following prolonged obstruction of the extrahepatic bile ducts the other is the consequence of a chronic intrahepatic inflammatory reaction due to a variety of factors some of which are still unknown These two types may be conveniently classified as follows

I Extrahepatic—due to partial or complete occlusion of the major bile ducts
II Intrahepatic
  A Primary—etiology unknown
  B Secondary—due to
    1 Viral hepatitis
    2 Drug sensitization reactions
    3 Hemochromatosis(?)

The *extrahepatic* type is seen most frequently following prolonged partial occlusion of the common *bile duct by postoperative stricture or stone* However it may be the result of congenital atresia carcinoma or benign cysts anywhere along the course of the biliary tract from the ampulla of Vater to the bifurcation of the hepatic duct in the porta hepatis provided the patient survives sufficiently long and the obstruction is not relieved There appear to be marked differences in individual susceptibility biliary cirrhosis occurring within a few months of obstruction in some instances and not for several years or not at all in others The question of whether biliary tract infection is a contributory factor is still unsettled

The *primary type of intrahepatic biliary cirrhosis* occurs almost exclusively in women Neither the etiology nor the reason for the unusual sex distribution is known However it is noteworthy that many of the patients have an allergic background and that the number of cases reported has increased since the introduction of the sulfonamides and other sensitizing drugs Since some of the latter have been implicated in the pathogenesis of the secondary type of intrahepatic biliary cirrhosis it is conceivable that unrecognized drug reactions are a more important etiologic factor in the primary type than is generally recognized Similarly unrecognized infections with the hepatitis virus may be a factor in some cases since it is known that they are capable of producing biliary cirrhosis

The secondary type of intrahepatic biliary cirrhosis appears to be the end stage of a progressive cholangiolitic hepatitis due either to the hepatitis virus (p 1491) or to drug hypersensitivity (p 1496) Thus typical cases have been reported following acute viral hepatitis and reactions to neoarsphenamine and neocinchophen and the author has seen it develop following reactions to the sulfonamides thiourea and phenobarbital Other drugs that produce a similar type of cholangiolitic hepatitis like chlorpromazine (Thorazine) and methyl testosterone have not yet been implicated but it is possible that they too will prove to be of etiologic importance

Rarely patients with hemochromatosis develop hypercholesteremia and xanthomatosis It is not known whether the hemosiderin deposits in such cases give rise to a form of biliary cirrhosis whether the lipid disturbance is merely an atypical manifestation of hemochromatosis or whether the hemosiderosis is secondary to an underlying biliary cirrhosis

At one time the primary intrahepatic type of

matory reaction The central veins are dilated and thickened and occasionally there is hemorrhage into the pericentral zone of degenerating liver cells Usually these changes are the consequence of the increase in hepatic venous pressure the stasis of blood and the hypoxia that follow congestive heart failure However very similar changes may be produced by occlusion of the hepatic veins (Chiari s syndrome) constriction of the pericardium and vascular shock

If congestion is prolonged and severe the pericentral zones of parenchymal atrophy and necrosis extend until adjacent central veins are bridged Since hepatocellular regeneration is relatively ineffective under these conditions the stroma tends to collapse forming bands of condensed and thickened reticulum fibers which ultimately undergo collagenization This gives rise to a reversal of the normal lobular pattern with centrally placed portal triads and perilobular rings of fibrous tissue joining adjacent central veins Later the zones of congestion atrophy and reticular collapse extend to the portal triads so that ultimately the lobular architecture is destroyed producing a picture which in its late stages may be indistinguishable from Laennec s cirrhosis As a rule there is little active regeneration so that the liver is finely granular and tends to diminish in size Occasionally however *particularly when bouts of severe congestion alternate* with periods of compensation regenerative nodules of varying size may be formed

Clinical Features In uncomplicated *chronic passive congestion* the liver is enlarged and tender and in long standing cases it may be firm even in the absence of fibrosis Pulsation of the liver is characteristic of tricuspid valvular disease Pressure over the liver often produces a significant increase in the distention of the jugular veins (hepatojugular reflux) Occasionally the spleen is enlarged but other signs of portal hypertension are rare although small asymptomatic esophageal varices may be observed at autopsy Many patients with congestive failure exhibit mild hyperbilirubinemia but frank jaundice and bilirubinuria are unusual except in patients with severe tricuspid valvular disease or in those with complicating pulmonary infarction The jaundice is primarily of hepatocellular origin but increased hemoly*sis may be a factor in cases with* pulmonary infarction Ascites is a common finding in advanced congestive failure No doubt the increase in hepatic venous pressure plays a role in its pathogenesis as it does in other conditions (p 148) but how much the accompanying hepatocellular injury contributes to the general phenomenon of salt and water retention in cardiac failure is still a matter of conjecture

The transition from chronic passive congestion of the liver to *cardiac cirrhosis* is a very gradual one and difficult to recognize clinically since the signs and symptoms in the two conditions are very much the same However intractable ascites a firm nontender liver absence of a demonstrable hepatojugular reflux and progressive splenomegaly are features that should suggest the diagnosis In contrast to other forms of cirrhosis deep jaundice spider nevi bleeding from esophageal varices and hepatic coma are unusual

While cardiac cirrhosis may occur in any type of heart disease it is seen most frequently in rheumatic heart disease severe cor pulmonale and constrictive pericarditis

Laboratory Features The most frequent functional abnormalities associated with congestion of the liver include Bromsulphalein retention, a slight rise in the serum bilirubin level an increase in urine urobilinogen and a fall in the serum albumin These characteristics parallel the severity of the hepatocellular changes However there is some evidence to indicate that Bromsulphalein retention may in part at least be a function of reduced hepatic blood flow In patients with overt jaundice the urine may contain bile Occasionally there is an increase in serum globulin cephalin-cholesterol flocculation and thymol turbidity

The changes in cardiac cirrhosis are very similar but the serum albumin concentration tends to fall *to a lower level*

Diagnosis The recognition of congestive hepatomegaly and cardiac cirrhosis is seldom difficult However they may be mistaken for other forms of cirrhosis when the signs of heart disease are masked as in constrictive pericarditis

Hemochromatosis

See p 718

Hepatolenticular Degeneration (Wilson s Disease)

See p 725

Cirrhosis Due to Schistosomiasis

Infestations with *Schistosoma mansoni* or *Schistosoma japonicum* may give rise to an unusual type of cirrhosis Although the disease is not indigenous to this country it is very common among Puerto Rican immigrants and is seen occasionally in Sec*ond World War veterans who served in the Pacific* area

Pathology Some of the schistosome ova deposited in the distal tributaries of the portal vein are swept back into the liver where they produce a granulomatous reaction in the portal triads the periportal parenchyma and the intrahepatic portal radicles themselves As the lesions age and become fibrotic the encapsulated ova degenerate Occasionally the process is confined to the larger intrahepatic periportal areas giving rise to so called white

palmar creases and over the skin of the neck chest and back Later more nodular tuberous lesions appear over the extensor surfaces of the knuckles elbows knees and ankles and over the buttocks

Another striking feature of this disease is steatorrhea due apparently to malabsorption of fat related to a decrease in bile salt excretion The stools tend to increase in frequency and occasionally are bulky foul and loose A more important complication is decalcification of bone which often is accompanied by compression of the vertebral bodies and back pain This appears to be the consequence of excessive fecal losses of vitamin D and calcium in relation to the steatorrhea but a postmenopausal defect in bone matrix formation may be involved in some cases It has been suggested that losses of other fat soluble vitamins and especially vitamin A may play a role in the pigmentation and thickening of the skin that occurs in this disease

In contrast to other forms of cirrhosis the patient feels remarkably well and loses little or no weight over a period of years despite the fact that the disease is progressive Also there is a striking absence of anorexia indigestion abdominal pain and tenderness chills and fever Ultimately however signs of hepatic failure (p 1501) or massive bleeding from esophageal varices appear Death may occur within 2 years but many patients live as long as 10 years Of interest is the fact that as hepatocellular failure develops there is a fall in the serum lipids and a disappearance or decrease in the size of the xanthomatous lesions

The clinical course in the other forms of biliary cirrhosis is very similar except that attacks of abdominal pain chills and fever and a history of antecedent gallbladder disease or biliary tract surgery are common in the extrahepatic type while an onset with typical acute viral hepatitis or a drug sensitization reaction is characteristic of the secondary intrahepatic type

Laboratory Features Early in the disease the principal findings are those of obstructive jaundice viz an elevated direct and total serum bilirubin a high serum alkaline phosphatase level increased serum cholesterol and phospholipid and a decrease in fecal urobilinogen Characteristically the serum is clear despite its high lipid content apparently because the concentration of neutral fat is not increased The serum albumin level is normal or only slightly decreased but falls when hepatocellular failure occurs However the serum globulins and especially the beta and gamma fractions are increased from the beginning The cephalin cholesterol flocculation reaction may be positive or negative but thymol turbidity is increased with regularity high values being especially common in patients with marked hypercholesteremia Despite steatorrhea and jaundice the prothrombin level is normal or if depressed is readily corrected by the parenteral administration of vitamin K

Diagnosis The possibility of biliary cirrhosis must be considered in any case of prolonged obstructive jaundice accompanied by significant hepatomegaly Once signs of portal hypertension or xanthomatosis appear the diagnosis can be made clinically with reasonable assurance but earlier in the disease biopsy of the liver may be necessary Usually the *most difficult problem is the distinction between* the extra and intrahepatic types Since this can seldom be made with certainty on clinical or even histologic grounds every patient with biliary cirrhosis deserves a thorough surgical exploration with cholangiography to exclude the presence of a remediable obstruction in the extrahepatic biliary tree

Treatment Surgical relief of biliary obstruction is essential in those with extrahepatic biliary cirrhosis If this can be accomplished remarkable improvement may be expected even when the disease is advanced

The objectives of treatment in the intrahepatic type of cirrhosis are the maintenance of nutrition the control and prevention of complications and the relief of pruritus

While a high protein high caloric diet is of value in maintaining weight and strength it appears to have little effect on the underlying hepatic lesion Fats need not be restricted unless steatorrhea becomes troublesome There is no evidence that limitation of dietary fat alters the course of the disease or the accompanying hypercholesteremia and xanthomatosis Daily supplements of vitamins A and D and a high calcium intake are indicated to compensate for fecal losses Vitamin K is administered if the prothrombin level is low It may be necessary to administer the fat soluble vitamins by the parenteral route if steatorrhea is severe

The management of ascites and bleeding esophageal varices is the same as in Laennec's cirrhosis (pp 1503 1504)

Pruritus is a difficult therapeutic problem Occasionally soothing lotions and baths and the antihistamine drugs are helpful but when itching is severe only methyltestosterone in daily doses of 25 mg sublingually appears to be effective Although it usually produces an increase in jaundice it has no long term ill effects Moreover it tends to lower the serum cholesterol and phospholipid levels and may thus prevent further xanthoma formation

Cardiac Cirrhosis

Pathology Characteristically the liver enlarges in congestive heart failure Microscopically there are engorgement of the pericentral sinusoids atrophy degeneration and necrosis of the intervening parenchymal cells and little or no inflam

matory reaction The central veins are dilated and thickened and occasionally there is hemorrhage into the pericentral zone of degenerating liver cells Usually these changes are the consequence of the increase in hepatic venous pressure the stasis of blood and the hypoxia that follow congestive heart failure However very similar changes may be produced by occlusion of the hepatic veins (Chiari s syndrome) constriction of the pericardium and vascular shock

If congestion is prolonged and severe the pericentral zones of parenchymal atrophy and necrosis extend until adjacent central veins are bridged Since hepatocellular regeneration is relatively ineffective under these conditions the stroma tends to collapse forming bands of condensed and thickened reticulum fibers which ultimately undergo collagenization This gives rise to a reversal of the normal lobular pattern with centrally placed portal triads and perilobular rings of fibrous tissue joining adjacent central veins Later the zones of congestion atrophy and reticular collapse extend to the portal triad so that ultimately the lobular architecture is destroyed producing a picture which in its late stages may be indistinguishable from Laennec s cirrhosis As a rule there is little active regeneration so that the liver is finely granular and tends to diminish in size Occasionally however particularly when bouts of severe congestion alternate with periods of compensation regenerative nodules of varying size may be formed

Clinical Features In uncomplicated *chronic passive congestion* the liver is enlarged and tender and in long standing cases it may be firm even in the absence of fibrosis Pulsation of the liver is characteristic of tricuspid valvular disease Pressure over the liver often produces a significant increase in the distention of the jugular veins (hepatojugular reflux) Occasionally the spleen is enlarged but other signs of portal hypertension are rare although small asymptomatic esophageal varices may be observed at autopsy Many patients with congestive failure exhibit mild hyperbilirubinemia but frank jaundice and bilirubinuria are unusual except in patients with severe tricuspid valvular disease or in those with complicating pulmonary infarction The jaundice is primarily of hepatocellular origin but increased hemolysis may be a factor in cases with pulmonary infarction Ascites is a common finding in advanced congestive failure No doubt the increase in hepatic venous pressure plays a role in its pathogenesis as it does in other conditions (p 148) but how much the accompanying hepatocellular injury contributes to the general phenomenon of salt and water retention in cardiac failure is still a matter of conjecture

The transition from chronic passive congestion of the liver to *cardiac cirrhosis* is a very gradual one and difficult to recognize clinically since the signs and symptoms in the two conditions are very much the same However intractable ascites a firm nontender liver absence of a demonstrable hepatojugular reflux and progressive splenomegaly are features that should suggest the diagnosis In contrast to other forms of cirrhosis deep jaundice spider nevi bleeding from esophageal varices and hepatic coma are unusual

While cardiac cirrhosis may occur in any type of heart disease it is seen most frequently in rheumatic heart disease severe cor pulmonale and constrictive pericarditis

Laboratory Features The most frequent functional abnormalities associated with congestion of the liver include Bromsulphalein retention, a slight rise in the serum bilirubin level an increase in urine urobilinogen and a fall in the serum albumin These characteristics parallel the severity of the hepatocellular changes However there is some evidence to indicate that Bromsulphalein retention may in part at least be a function of reduced hepatic blood flow In patients with overt jaundice the urine may contain bile Occasionally there is an increase in serum globulin cephalin cholesterol flocculation and thymol turbidity

The changes in cardiac cirrhosis are very similar but the serum albumin concentration tends to fall to a lower level

Diagnosis The recognition of congestive hepatomegaly and cardiac cirrhosis is seldom difficult However they may be mistaken for other forms of cirrhosis when the signs of heart disease are masked as in constrictive pericarditis

Hemochromatosis

See p 718

Hepatolenticular Degeneration (Wilson s Disease)

See p 725

Cirrhosis Due to Schistosomiasis

Infestations with *Schistosoma mansoni* or *Schistosoma japonicum* may give rise to an unusual type of cirrhosis Although the disease is not indigenous to this country it is very common among Puerto Rican immigrants and is seen occasionally in Second World War veterans who served in the Pacific area

Pathology Some of the schistosome ova deposited in the distal tributaries of the portal vein are swept back into the liver where they produce a granulomatous reaction in the portal triads the periportal parenchyma and the intrahepatic portal radicles themselves As the lesions age and become fibrotic the encapsulated ova degenerate Occasionally the process is confined to the larger intrahepatic periportal areas giving rise to so-called white

pipestem fibrosis which mimics cirrhosis clinically but differs from it in that the remaining parenchyma is intact However many patients with hepatic schistosomiasis develop a fine nodular cirrhosis of the Laennec s type In some patients this appears to be the consequence of a widespread granulomatous reaction to ova but in others the etiology is uncertain and may be related to accompanying malnutrition

Clinical Features The principal findings in hepatic schistosomiasis are progressive enlargement of the liver and signs of portal hypertension Bleeding from esophageal varices is a frequent complication while signs of hepatocellular failure are relatively uncommon except in patients with malnutrition in whom the disease behaves more like Laennec s cirrhosis

Some patients have frank signs of intestinal schistosomiasis but many of the Puerto Ricans seen in this country who present with hepatomegaly or esophageal bleeding have no other clinical manifestations of the disease and often have had no exposure to infestation for many years Often rectal biopsy is positive for ova but if not the diagnosis can usually be established by means of needle biopsy of the liver

For a more complete discussion of schistosomiasis see p 1130

Rare Forms of Cirrhosis

Granulomatous Cirrhosis Occasionally granulomatous diseases are accompanied by cirrhosis In the case of sarcoidosis (p 1498) it is reasonably certain that the cirrhosis follows healing of extensive granulomatous lesions but in tuberculosis (p 1498) and brucellosis (p 1499) it is doubtful that the cirrhosis is of granulomatous origin Rarely the diffuse hepatitis of congenital syphilis gives rise to a fine diffuse fibrosis of the liver However there is no evidence that the acquired form of syphilis ever produces cirrhosis

Cirrhosis Associated with Metabolic Disorders A significant number of patients with *diabetes mellitus* have fatty livers and a few develop a lesion resembling Laennec s cirrhosis Many authorities attribute the fatty infiltration to obesity starvation or poor regulation of the diabetes and regard the association of diabetes and cirrhosis as fortuitous However this opinion is not shared by all investigators so that the pathogenesis of cirrhosis in diabetes is still an unsettled problem

Rarely *hyperthyroidism* is accompanied by cirrhosis It is generally believed that the cirrhosis is the consequence of congestive heart failure but it has been suggested that in some instances it may be the result of a specific circulatory disturbance an induced nutritional deficiency or a relative hypoxia related to the hyperthyroid state

Not infrequently infants with *galactosemia* a congenital disease in which galactose cannot be metabolized develop an hepatic lesion resembling Laennec s cirrhosis This has been attributed to the toxic action of galactose or to a nutritional deficiency related to the inability to utilize the galactose in milk However galactose does not produce hepatic injury in animals and the character of the lesions and the rapidity with which they appear in affected infants are not typical of nutritional deficiency so that neither of the theories appears tenable

Rarely *von Gierke s disease* (p 731) is associated with cirrhosis

As previously noted (p 1505) the *de Toni Fanconi syndrome* is occasionally accompanied by a coarsely nodular cirrhosis The pathogenesis of the hepatic lesion is unknown A nutritional deficiency related to the loss of amino acids has been postulated but the evidence for this is not convincing

Erythroblastosis Fetalis Often the liver is severely injured in erythroblastosis and rarely cirrhosis is a sequela On the basis of indirect evidence it has been suggested that other forms of infantile or juvenile cirrhosis may be the consequence of other unrecognized maternal blood incompatibilities

Infiltrations of the Liver

Fatty Liver Usually fatty infiltration of the liver is due to a deficiency of lipotropic substances secondary to faulty dietary habits chronic alcoholism absorptive defects or the malnutrition of certain chronic wasting diseases However it is seen also in metabolic disorders like diabetes mellitus and galactosemia in obesity and as a transient phenomenon in poisoning with agents like carbon tetrachloride and phosphorus The pathogenesis in the latter group is uncertain Except in the case of obesity long continued fatty infiltration appears to predispose to the development of cirrhosis

Often the fatty liver is enlarged to palpation and not infrequently there is mild Bromsulphalein retention Other signs of hepatocellular failure and portal hypertension do not occur unless there is accompanying hepatic necrosis or fibrosis

Hemosiderosis Usually abnormal deposits of hemosiderin in the liver are a sign of increased total body stores of iron This may be the result of an excessive uptake of iron from the gastrointestinal tract due to (1) a congenital absorptive defect as in hemochromatosis (2) the stimulus of chronic anemia with failure to utilize the absorbed iron as in certain hemolytic states (3) an excessive intake of iron (4) the use of low protein low phosphate diets that enhance iron absorption or (5) the transfusion of large amounts of blood

Uncomplicated hemosiderosis of the liver produces no symptoms The question of whether the fibrosis seen in advanced cases is the result of hepatocellular degeneration related to excessive storage of iron is still unsettled

The reader is referred to the chapter on hemochromatosis (p 718) for a more complete discussion of this subject

Glycogen Storage (von Gierke s) Disease See p 731

Amyloidosis The liver is involved in a high proportion of patients with secondary amyloidosis and somewhat less frequently in those with primary amyloidosis and the type associated with multiple myeloma Amyloid is deposited between the sinusoids and the parenchymal cells slowly obliterating the former and causing atrophy of the latter In addition the walls of the blood vessels may be infiltrated especially in the primary type

The liver is enlarged smooth and firm Jaundice spider nevi and ascites are rare except in advanced cases Portal hypertension is not a feature but the spleen may be enlarged as a result of amyloid deposition The remaining clinical signs and symptoms relate to involvement of other tissues and are described elsewhere (p 720)

Despite extensive infiltration of the liver hepatocellular function tends to be little deranged except for slight Bromsulphalein retention Hypoalbuminemia and hypercholesteremia common in advanced cases appear to be more closely related to the accompanying nephrotic syndrome Hyperglobulinemia is an inconstant finding and usually the cephalin cholesterol and thymol turbidity reactions are normal Occasionally high levels of serum alkaline phosphatase are seen

Lymphomatous and Other Reticuloendothelial Infiltrations Not infrequently the liver participates in the abnormal generalized reticuloendothelial reactions that characterize *leukemia Hodgkin s disease* and *lymphosarcoma* Whether the hepatic lesions represent infiltrations from without or a local reticuloendothelial reaction to the underlying stimulus is not clear Hepatomegaly is the principal finding apart from the other manifestations of the underlying disease and except for jaundice rarely is accompanied by other signs or symptoms of hepatocellular failure While jaundice may occur in any of these conditions it is most common in Hodgkin s disease where it usually is due to a combination of biliary obstruction and parenchymal destruction Occasionally a hemolytic process is involved

In *extramedullary hematopoesis* the liver may be enlarged owing to infiltration of the sinusoids and portal triads with megakaryocytes and immature erythrocytes and leukocytes Marked splenomegaly is an invariable accompaniment The disease represents a reversion to a fetal type of hematopoietic activity in response to aplasia or replacement of the normal bone marrow The hepatic lesions seldom give rise to any symptoms the principal manifestations being related to the underlying bone marrow disease

Gaucher s disease and *Niemann Pick disease* are hereditary disorders characterized by a generalized proliferation of abnormal reticuloendothelial cells containing lipid a cerebroside (kerasin) in the former and a phospholipid (sphingomyelin) in the latter In both diseases the liver and spleen are infiltrated with these cells resulting in hepatomegaly and splenomegaly The hepatic lesions give rise to no symptoms the clinical manifestations being due to involvement of other tissues (p 744)

Space-occupying Lesions

Primary Carcinoma of the Liver Carcinomas that arise in the liver may be derived from either the parenchymal cells or the intrahepatic bile duct epithelium and are known respectively as *hepatomas* and *cholangiomas* The former are twice as common as the latter Occasionally tumors show features of both types

Males are affected more frequently than females and the onset is more common after the age of fifty although the disease may occur in children and young adults The incidence is particularly high in areas where nutritional and parasitic disease of the liver is endemic Thus in this country primary hepatic carcinomas comprise only 2 5 per cent of all malignancies while in South Africa China and Malaya the incidence among natives ranges from 50 to 30 per cent

Cirrhosis appears to be an important predisposing factor and is found in approximately 75 per cent of patients with hepatoma and 50 per cent of those with cholangioma While the incidence of primary hepatic carcinoma is only 0 3 per cent in routine autopsies it is approximately 4 per cent in the cirrhotic group and almost twice that in hemochromatosis

Often the clinical picture is that of the underlying cirrhosis so that the presence of a complicating hepatoma may be overlooked In the person known to have cirrhosis the possibility of this complication should be considered when (1) jaundice ascites or bleeding from esophageal varices occurs without provocation in a patient without previous signs of hepatic decompensation, (2) abdominal pain is a prominent feature (3) the liver is unusually large and tender has large palpable nodules on its surface is enlarged asymmetrically or has an overlying friction rub or vascular bruit (4) there is rapid weight loss out of keeping with the dietary intake (5) high fever and leukocytosis are present

(6) the serum alkaline phosphatase level is unusually high or (7) the ascitic fluid is bloody It must be emphasized that these features are not seen in all cases and indeed some are relatively uncommon Jaundice occurs in only half the patients and may be due to obstruction of bile ducts or to extensive destruction of the parenchyma Ascites and esophageal bleeding are frequent but inconstant features While they may be related to the accompanying cirrhosis the tendency of the tumor to invade the hepatic and portal veins appears to be an important factor in many cases High fever marked leukocytosis friction rubs and bruits are *unusual but are important clues* when present A high alkaline phosphatase level is not a constant finding but is highly suggestive of intrahepatic malignancy particularly in the absence of jaundice Bloody ascitic fluid is seen occasionally in uncomplicated Laennec s cirrhosis but is more common in the presence of malignancy

In the absence of overt signs of cirrhosis the diagnosis may be very difficult since cachexia abdominal pain jaundice ascites and hepatomegaly are features common to other forms of intra-abdominal malignancy with metastases to the liver and peritoneum There is a clinical impression that hepatomas rarely metastasize However this is not borne out by autopsy studies which indicate that metastases occur in approximately 65 per cent of cases the sites of predilection being the periportal and peripancreatic lymph nodes the lungs and pleura the peritoneum the bones the brain and the adrenal glands Occasionally symptoms referable to bony metastases are the first to appear

Needle biopsy of the liver is an important diagnostic aid and is positive in a high proportion of cases X ray studies are useful in excluding primary carcinomas in other sites and occasionally are helpful in establishing the presence of an intrahepatic mass by demonstrating a localized elevation *of the right leaf of the diaphragm*

The outlook is virtually hopeless most patients dying within a few months to a year Successful excision of carcinoma localized to a single lobe *has been reported but this is a rarity since the* tumor has usually spread by way of the intrahepatic vessels to involve the entire liver by the time the disease is recognized clinically

Other Primary Tumors of the Liver *Hemangiomas* are the most common tumors encountered in the liver Usually they are small and asymptomatic but occasionally they are large or very numerous *producing* hepatic enlargement or localized swelling of the liver Females are affected more frequently than males and left lobe involvement is more common than right When the tumor is large it may produce pain or may give rise to a fatal hemorrhage into the peritoneal cavity either spontaneously or following trauma Occasionally obstructive jaundice is a complication and rarely congestive heart failure is the result of extensive arteriovenous shunting of blood through the tumor An hepatic bruit is audible in some cases and not infrequently calcification is demonstrable radiographically *Successful* surgical removal of localized hemangiomas is possible and is generally recommended to prevent massive hemorrhage and to relieve pressure symptoms

Malignant *hemangioendotheliomas* and other forms of *sarcoma* are very rare

Metastatic Neoplasms of the Liver These occur at least twenty times as frequently as primary carcinoma of the liver and they constitute a more important problem since hepatic metastases are found in approximately one third of all malignancies

The liver appears to provide a peculiarly favorable environment for the growth of tumor cells and by virtue of its double circulation is in a strategic position to trap metastasizing cells gaining access to either the portal venous or hepatic arterial blood stream In addition retrograde invasion of its lymphatics from adjacent organs is possible As might be expected malignancy arising in the distribution of the portal vein such as gastrointestinal and pancreatic carcinoma metastasizes to the liver more commonly than to the lung However it is surprising to find that the same is true of tumors arising in the breast uterus ovary and kidneys whose venous drainage reaches the lungs first Only in the case of thyroid and prostatic carcinoma is pulmonary involvement more common Whether tumor cells pass through the lung and reach the liver by way of the arterial circulation or extend to contiguous tissues drained by the portal vein is uncertain In the case of the breast it is believed that metastasis occurs by way of lymphatics

Metastases are usually multiple and once implanted tend to grow rapidly invading blood vessels and lymphatics and extending to other parts of the liver Not infrequently the growth of tumor tissue in the liver is far more conspicuous than at the primary site and indeed the clinical manifestations may be predominantly hepatic at a time when the primary lesion is not detectable This is particularly true of carcinomas arising in the pancreas gallbladder kidney and lung and of melanosarcomas

The clinical features vary depending on the extent and location of the lesion At one extreme there may be no signs or symptoms suggestive of metastasis while at the other invasion may be so extensive that signs of hepatocellular failure and portal obstruction are produced In general however the latter are uncommon even when widespread hepatic metastases are present

Sooner or later weight loss anorexia abdominal pain and hepatomegaly develop Usually the liver is very hard because of the fibrotic reaction frequently associated with malignant infiltration, and often nodules are palpable Although the liver is not palpable in all instances it tends to enlarge progressively as the disease advances and occasionally it grows to tremendous size Rarely an overlying friction rub may be audible Jaundice is an inconstant and late finding and may be due to obstruction of major bile ducts, either within the liver or at the porta hepatis or less commonly to hepatocellular failure Usually ascites follows spread of the tumor to the peritoneum but it may be the result of invasion of the hepatic or portal vein, severe hypoalbuminemia or hepatic decompensation Splenomegaly occurs in 10 to 15 per cent of cases It is said to be especially common in pancreatic carcinoma because of splenic vein obstruction but in the writer's experience splenomegaly has not been limited to this particular type of tumor and usually has been due to massive invasion of the liver producing portal hypertension Esophageal varices and massive upper gastrointestinal bleeding have been complications in a few such cases

Hepatocellular function may be completely normal, even in the face of extensive metastasis However Bromsulphalein retention and a significant elevation of serum alkaline phosphatase are common findings Usually cephalin-cholesterol flocculation and thymol turbidity are normal except very late in the disease Often the serum albumin level is lowered, but this may be the consequence of malnutrition The high alkaline phosphatase level is of particular diagnostic significance in the absence of jaundice and signs of bone involvement it should suggest the possibility of hepatic malignancy or some other type of infiltration

Short of surgical exploration needle biopsy of the liver is by far the most useful and accurate diagnostic aid in this disease Approximately 80 per cent of hepatic metastases can be demonstrated by this technique not infrequently in the absence of any overt signs of the disease Considering the focal character of the gross lesions seen at the autopsy and their scattered distribution this incidence appears incredible However the infiltration usually is much more diffuse than is evident on macroscopic examination because of the tendency of the tumor to spread along vascular channels

Amebic Abscess See p 1109

Pyogenic Abscess The incidence of pyogenic abscess which has always been lower than that of the amebic variety has declined appreciably since the introduction of antibiotic therapy in the management of infections that predispose to abscess formation

Almost always pyogenic abscess of the liver is the result of parenchymal invasion by organisms stemming from an adjacent or distant septic focus However the source of infection may be difficult to detect and rarely the infection is primary in the liver as a result of a penetrating or crushing wound Organisms may gain access to the liver via the portal vein hepatic artery or lymphatics or by direct extension from the biliary tract or other contiguous structures

Any suppurative focus in the drainage area of the portal vein may give rise to an hepatic abscess At one time acute appendicitis was the most frequent offender but it has been superseded by biliary tract infection probably because the latter is less amenable to chemotherapy Usually there is an initial local thrombophlebitis from which organisms are fed into the liver either by embolization or by direct extension of the phlebitic process to the portal vein and its intrahepatic radicles (pylephlebitis)

Direct extension of infection to the hepatic parenchyma occurs most commonly in suppurative cholangitis associated with biliary obstruction, but it may also follow rupture of the gallbladder perforation of a peptic ulcer pancreatic abscess or other conditions leading to subhepatic or subphrenic suppuration No doubt spread of infection by way of the lymphatics or portal radicles is an additional factor in many such cases

Rarely pyogenic infections are the result of bacterial embolization by way of the hepatic artery in hematogenous infections associated with osteomyelitis bacterial endocarditis or pulmonary disease

The lesions may be single or multiple the latter occurring more frequently when the infection has spread by way of the biliary tract or the vessels Occasionally small abscesses coalesce to form a large solitary lesion The right lobe is involved more often than the left

Most pyogenic abscesses of the liver are due to infection with *E coli* streptococci, staphylococci or Friedlander's bacilli but occasionally *Cl welchii Pseudomonas aeruginosa Salmonella* gonococci *Bacteroides funduliformis* and other agents are implicated

The principal symptoms are those of sepsis namely recurrent chills and fever sweats prostration, anorexia, nausea, vomiting and weight loss In addition there are signs pointing to involvement of the liver including abdominal pain distention and hepatic enlargement and tenderness Usually the pain is aching in character and localized over the hepatic area or epigastrium and not infrequently it radiates to the right shoulder and is aggravated by respiration Percussion and compression of the liver are painful Occasionally a large abscess may be palpable as a localized mass beneath

(6) the serum alkaline phosphatase level is unusually high or (7) the ascitic fluid is bloody It must be emphasized that these features are not seen in all cases and indeed some are relatively uncommon Jaundice occurs in only half the patients and may be due to obstruction of bile ducts or to extensive destruction of the parenchyma Ascites and esophageal bleeding are frequent but inconstant features While they may be related to the accompanying cirrhosis the tendency of the tumor to invade the hepatic and portal veins appears to be an important factor in many cases High fever marked leukocytosis friction rubs and bruits are unusual but are important clues when present A high alkaline phosphatase level is not a constant finding but is highly suggestive of intrahepatic malignancy particularly in the absence of jaundice Bloody ascitic fluid is seen occasionally in uncomplicated Laennec s cirrhosis but is more common in the presence of malignancy

In the absence of overt signs of cirrhosis the diagnosis may be very difficult since cachexia abdominal pain jaundice ascites and hepatomegaly are features common to other forms of intraabdominal malignancy with metastases to the liver and peritoneum There is a clinical impression that hepatomas rarely metastasize However this is not borne out by autopsy studies which indicate that metastases occur in approximately 65 per cent of cases the sites of predilection being the periportal and peripancreatic lymph nodes the lungs and pleura the peritoneum the bones the brain and the adrenal glands Occasionally symptoms referable to bony metastases are the first to appear

Needle biopsy of the liver is an important diagnostic aid and is positive in a high proportion of cases X ray studies are useful in excluding primary carcinomas in other sites and occasionally are helpful in establishing the presence of an intrahepatic mass by demonstrating a localized elevation of the right leaf of the diaphragm

Short of surgical exploration needle biopsy of the liver is by far the most useful and accurate diagnostic aid in this disease Approximately 80 per cent of hepatic metastases can be demonstrated by this technique not infrequently in the absence of any overt signs of the disease Considering the focal character of the gross lesions seen at the autopsy and their scattered distribution this incidence appears incredible However the infiltration usually is much more diffuse than is evident on macroscopic examination because of the tendency of the tumor to spread along vascular channels

Amebic Abscess See p 1109

Pyogenic Abscess The incidence of pyogenic abscess which has always been lower than that of the amebic variety has declined appreciably since the introduction of antibiotic therapy in the management of infections that predispose to abscess formation

Almost always pyogenic abscess of the liver is the result of parenchymal invasion by organisms stemming from an adjacent or distant septic focus However the source of infection may be difficult to detect and rarely the infection is primary in the liver as a result of a penetrating or crushing wound Organisms may gain access to the liver via the portal vein hepatic artery or lymphatics or by direct extension from the biliary tract or other contiguous structures

Any suppurative focus in the drainage area of the portal vein may give rise to an hepatic abscess At one time acute appendicitis was the most frequent offender but it has been superseded by biliary tract infection probably because the latter is less amenable to chemotherapy Usually there is an initial local thrombophlebitis from which organisms are fed into the liver either by embolization or by direct extension of the phlebitic process to the portal vein and its intrahepatic radicles (pylephlebitis)

Direct extension of infection to the hepatic parenchyma occurs most commonly in suppurative cholangitis associated with biliary obstruction, but it may also follow rupture of the gallbladder perforation of a peptic ulcer pancreatic abscess or other conditions leading to subhepatic or subphrenic suppuration No doubt spread of infection by way of the lymphatics or portal radicles is an additional factor in many such cases

Rarely pyogenic infections are the result of bacterial embolization by way of the hepatic artery in hematogenous infections associated with osteomyelitis bacterial endocarditis or pulmonary disease

The lesions may be single or multiple the latter occurring more frequently when the infection has spread by way of the biliary tract or the vessels Occasionally small abscesses coalesce to form a large solitary lesion The right lobe is involved more often than the left

Most pyogenic abscesses of the liver are due to infection with *E coli* streptococci staphylococci or Friedlander s bacilli but occasionally *Cl welchii Pseudomonas aeruginosa Salmonella* gonococci *Bacteroides fundiliformis* and other agents are implicated

The principal symptoms are those of sepsis namely recurrent chills and fever sweats prostration anorexia nausea vomiting and weight loss In addition there are signs pointing to involvement of the liver including abdominal pain distention and hepatic enlargement and tenderness Usually the pain is aching in character and localized over the hepatic area or epigastrium and not infrequently it radiates to the right shoulder and is aggravated by respiration Percussion and compression of the liver are painful Occasionally a large abscess may be palpable as a localized mass beneath

the costal margin or may cause fullness and tenderness of the intercostal spaces When the abscess is located high in the right lobe secondary involvement of the diaphragm and pleura may ensue giving rise to cough splinting of the chest pleural effusion and signs of atelectasis On x ray examination the diaphragm is elevated and fixed the cardiophrenic angle is blunted and occasionally a local bulge can be made out If a gas producing organism is present it may be possible to demonstrate fluid levels within the abscess Jaundice is not a prominent feature except in multiple abscess associated with suppurative cholangitis or pylephlebitis Usually its presence denotes a grave prognosis

In addition to the signs of hepatic abscess there may be others related to (1) the underlying source of infection such as acute appendicitis (2) concomitant metastatic suppurative foci in the lungs spleen kidney or brain or (3) any of the complications of hepatic abscess including peritonitis subphrenic abscess empyema lung abscess and bronchohepatic fistula

Usually the patient is acutely ill but solitary abscesses may encapsulate and run a more indolent course characterized by low grade fever sweats wasting and abdominal pain

Marked leukocytosis and an increase in the percentage of polymorphonuclear cells are the outstanding laboratory features Liver function test results may be normal but in patients with jaundice the concentrations of serum bilirubin and alkaline phosphatase are increased With prolonged infection the serum albumin level falls and the globulin rises

Most pyogenic abscesses of the liver can be prevented by prompt use of antibiotics and appropriate surgical measures in the treatment of intraabdominal infections Once the abscess has developed surgical drainage and intensive antibiotic therapy are indicated Unfortunately drainage is seldom successful when multiple abscesses are present However in those abscesses associated with suppurative cholangitis drainage of the extrahepatic bile ducts may be effective

Gumma Gummas the necrotic masses of conglomerate granulomas seen in late syphilis are rare at present In the liver they give rise to deep scars as they heal and if multiple may produce the type of deformity known as *hepar lobatum* Solitary lesions seldom produce symptoms However hepar lobatum while not a form of cirrhosis since the lobular pattern of the remaining parenchyma is normal occasionally produces signs of portal hypertension ascites and jaundice Pain and low grade fever are prominent in some cases Usually the liver is palpable and coarsely nodular Predominant involvement of the left lobe is said to be characteristic but this is denied by many authorities Liver function is little deranged except terminally

Echinococcus Cyst See p 1139

Polycystic Disease As a result of a congenital developmental defect isolated segments of the intrahepatic bile ducts may undergo cystic change within the trabeculae of the liver The cysts vary in size and number and if numerous may cause great enlargement and honeycombing of the liver In approximately half the cases there are associated *polycystic lesions in other organs including the* kidney spleen pancreas and lungs

As a rule hepatic cysts give rise to no symptoms Occasionally however the liver enlarges during middle age and by exerting pressure on adjacent structures produces pain and gastrointestinal symptoms Rarely portal hypertension is a complication

Functional Disorders of Unknown Etiology

Constitutional Hyperbilirubinemia (Synonyms *congenital hyperbilirubinemia familial nonhemolytic jaundice chronic intermittent juvenile jaundice Gilbert's cholémie simple familiale*) This condition is characterized by a mild intermittent jaundice without other evidence of hepatic or hemolytic disease which often is accompanied by lassitude and vague gastrointestinal complaints It occurs at all ages but is most frequent in young adults Excessive fatigue overindulgence in alcohol infection and surgical trauma appear to be the factors most commonly involved in precipitating relapses Usually there are no physical findings of note although slight hepatomegaly is seen in some cases The serum bilirubin level seldom rises above 5 mg per 100 ml and characteristically the increase is in the indirect reacting fraction as in hemolytic jaundice However there is no increase in urine or fecal urobilinogen reticulocytosis or other evidence of increased hemolysis No bilirubin is excreted in the urine and the color of the stools remains normal Except for the hyperbilirubinemia no other abnormalities of hepatic function can be demonstrated and a cholecystogram usually reveals a normal gallbladder On histologic examination the liver appears to be normal although occasionally a mild degree of fatty infiltration may be found

Although the symptoms recur over a period of years they tend to regress with advancing age and never are followed by signs of progressive hepatic disease As a rule there is little disability but often the jaundice is a matter of great concern to both the patient and his physician unless its nature is recognized

The jaundice appears to be due to a reduction in the capacity of the otherwise normal parenchymal cells to excrete bilirubin Recent evidence indicates

that this is related to an enzymatic defect partially blocking the conversion of indirect reacting bilirubin to its glucuronide Since other members of the family are similarly affected in approximately half the cases that are recognized it is believed that the defect is inherited as a dominant characteristic However it should be noted that a very similar syndrome may follow an attack of acute viral hepatitis so that the enzymatic defect may be acquired in some instances

Unfortunately this syndrome is not well known to clinicians so that often it is mistaken for relapsing hepatitis or hemolytic icterus The features that should suggest the diagnosis include a mild hyperbilirubinemia of the indirect type absence of clinical or laboratory evidence of liver disease absence of signs of increased hemolysis and a benign relapsing clinical course Occasionally liver biopsy is needed for confirmation

Attempts to treat this disease with cortisone and ACTH have been unsuccessful

Chronic Idiopathic Jaundice with Pigmentation of the Liver (Dubin Johnson Syndrome) As in constitutional hyperbilirubinemia this disease affects young individuals and is characterized by a chronic intermittent jaundice However in contrast the increase in serum bilirubin is of the direct reacting type there are other associated abnormalities of hepatic function and histologically the liver shows a curious type of pigmentation which is pathognomonic

Usually the onset is insidious but in approximately a third of the patients it is acute and simulates an attack of acute viral hepatitis The chief complaints are jaundice right upper quadrant pain anorexia nausea vomiting weakness and fatigability The liver may be enlarged and tender and when inspected during surgical exploration appears dark brown or green black in color On histologic examination a highly characteristic coarsely granular brown pigment is found in the centrilobular parenchymal cells The nature of this pigment is not known but it does not appear to be bilirubin hemosiderin ceroid or any of the known lipochromes It has been suggested that it may be a derivative of bilirubin a dipyrrolic breakdown product of hemoglobin or an oxidation product of polymerized unsaturated fatty acids Usually the liver shows no other abnormalities although the portal triads may contain a small number of mononuclear cells

The principal laboratory findings are a slight to moderate increase in serum bilirubin and a mild degree of Bromsulphalein retention Approximately half the bilirubin reacts directly Often at the height of the jaundice the urine contains bile and an increased amount of urobilinogen Occasionally cephalin cholesterol flocculation and thymol turbidity are abnormal but usually the levels of serum protein cholesterol and alkaline phosphatase remain within normal limits On cholecystography the gallbladder fails to fill with dye

In the small number of cases reported thus far there has been no evidence of progressive hepatic damage although the disease has shown no tendency to abate over a period of years

It has been suggested that the disease is due to an inborn error in metabolism leading to a defect in the capacity of the liver to excrete bilirubin Bromsulphalein cholecystography dyes and the unusual pigment found in the liver However there is no evidence that the disease is either congenital or hereditary and the possibility that the excretory defect is acquired as a result of viral hepatitis or other inflammatory disease of the liver has not been excluded

It is difficult if not impossible to differentiate this condition from the various forms of chronic hepatitis and low grade extrahepatic biliary obstruction on clinical grounds alone so that liver biopsy is essential for diagnosis

Familial Nonhemolytic Jaundice in the Newborn Crigler and Najjar have described a rare form of jaundice in newborn infants which is characterized by a high level of indirect reacting bilirubin in the serum and the frequent occurrence of kernicterus as in erythroblastosis fetalis However in contrast there is no evidence of increased hemolysis Except for the inability to excrete bilirubin, hepatic function is not altered and histologically the liver appears normal but usually shows bile thrombi in the canaliculi The prognosis is grave most affected infants dying within the first year of life

Thus far all the cases recognized have had a common ancestor suggesting that the disease is hereditary and possibly due to a genetically determined disturbance in the excretory function of the hepatic parenchyma In many respects the disease resembles familial hyperbilirubinemia but the striking differences in incidence age distribution central nervous system involvement and prognosis suggest that the two conditions are unrelated

HEPATOBILIARY DISEASE

Extrahepatic Biliary Obstruction Any obstruction to the outflow of bile from the ampulla of Vater to the bifurcation of the common hepatic duct at the hilum of the liver will result in jaundice Since the excretory capacity of the liver for bilirubin greatly exceeds the normal demands made upon it uncomplicated occlusion of the right or left hepatic duct alone does not produce jaundice The pathogenesis of the jaundice and the nature of the associated hepatic lesions have been described elsewhere (p 145)

The most frequent causes of obstruction include stone stricture congenital atresia carcinoma of the bile duct and carcinoma of the head of the pancreas Extrinsic pressure by malignant cystic or inflammatory masses enlarged hepatic hilar lymph nodes or inflammatory reactions in the pancreas may constrict the duct but this occurs less frequently than is generally believed Even in the case of carcinoma of the head of the pancreas invasion of the duct wall appears to be a more important factor than extrinsic pressure Choledochal cyst and invasion of the biliary tree by *Ascaris lumbricoides* are rare causes of obstructive jaundice

The obstruction is rarely complete except in the case of congenital atresia and malignancy and even in the latter it may be incomplete for some time and may fluctuate in degree as a result of inflammatory swelling and necrosis of the tumor

Usually the *onset* of obstructive jaundice is gradual but it may be sudden when the common duct is occluded by stone or when a partial obstruction is complicated by an acute cholangitis Nevertheless the jaundice rarely deepens with the rapidity seen in acute viral hepatitis since the interruption of bile flow is seldom so sudden or complete The depth of jaundice ultimately attained depends on the degree and duration of the obstruction and to some extent on the presence or absence of complicating cholangitis and hepatocellular injury The most intense forms of jaundice are seen in malignant obstruction and not infrequently are associated with a greenish tint to the skin and sclerae due to the presence of biliverdin The course of the jaundice is variable depending on the nature of the obstruction However it seldom follows the regular pattern seen in acute viral hepatitis (p 1488)

Pruritus is a common feature but is not pathognomonic of obstructive jaundice occurring as a transient phenomenon in viral hepatitis and as a more persistent symptom in primary hepatic biliary cirrhosis Usually the *urine darkens* because of the presence of bilirubin and if the obstruction is reasonably complete the *stools* become *clay colored*

If the obstruction is sustained the *liver enlarges* and may be *tender* Often in carcinomatous obstruction of the common duct the *gallbladder* is *distended* and *palpable* This is unusual when stone or stricture is present since the gallbladder is apt to be contracted as a result of chronic inflammation and scarring (Courvoisier s law) Occasionally the gallbladder is palpable because it contains numerous large stones is distended by an impacted stone in the cystic duct (hydrops) or is the site of carcinomatous infiltration Splenomegaly is unusual except when the obstruction is due to carcinoma of the pancreas or is associated with extensive intrahepatic metastases

Fever particularly if accompanied by recurrent *chills* usually indicates the presence of a complicating ascending cholangitis However it may be related to an underlying malignancy

Pain is an inconstant feature in obstructive jaundice and may be due to the presence of stone acute cholangitis carcinoma or other complicating disease The occurrence of typical biliary colic almost always points to a common duct stone However not infrequently stones produce obstruction without inducing pain In acute cholangitis which may accompany either a common duct stone or a stricture the pain tends to be more constant and is located either in the epigastrium or over the liver itself As a rule the onset of carcinomatous obstructive jaundice is painless but frequently as the disease progresses and the underlying tumor invades adjacent structures pain is produced

Other clinical and diagnostic features related to the specific diseases that give rise to obstructive jaundice are described in the chapter that follows

The principal *laboratory features* include hyperbilirubinemia with a high proportion of the direct reacting fraction bilirubinuria and significant elevation of the serum alkaline phosphatase and cholesterol levels Fecal urobilinogen is decreased and if the obstruction is complete as in carcinoma the daily excretion is less than 5 mg Usually urine urobilinogen is decreased or absent but if cholangitis is present it may be increased owing to the production and reabsorption of urobilinogen in the biliary tract Cephalin cholesterol flocculation and thymol turbidity are normal early in uncomplicated biliary obstruction but often they are abnormal and may be accompanied by hypoalbuminemia and hyperglobulinemia when acute cholangitis is present or when the obstruction is prolonged These changes relate both to infection and to hepatocellular injury The prothrombin concentration tends to fall it will usually rise following the parenteral administration of vitamin K

Acute cholangitis biliary cirrhosis and hepatic abscess are the chief complications of biliary obstruction

Once the diagnosis of extrahepatic biliary obstruction is firmly established the *treatment* of choice is surgical relief of the obstruction and antibiotic therapy for any accompanying inflammatory process A brief period of watchful waiting is warranted in the case of common duct stone since the latter may pass spontaneously and in the case of certain inflammatory obstructive lesions such as pancreatitis which may subside spontaneously or following appropriate chemotherapy Conservative therapy is indicated also in patients with common duct stricture who have been subjected to repeated plastic procedures and who are not likely to benefit from further attempts at repair Not infrequently the obstructive symptoms in such cases are due to a

superimposed cholangitis which may respond to antibiotics

Cholangitis Acute cholangitis of bacterial origin is almost always a complication of (1) bile stasis due to extrahepatic biliary obstruction by stone stricture or carcinoma (2) spread of infection from adjacent structures such as the gallbladder and pancreas (3) enteric infections like typhoid and paratyphoid fever or (4) parasitic invasion of the bile ducts with *A lumbricoides* liver flukes (*Clonorchis sinensis* and *Fasciola hepatica*) or *Giardia lamblia* Common duct stone is by far the most frequent cause of acute cholangitis while enteric infections and parasitic infestations are of little etiologic importance in this part of the world The relationship between cholangitis and pancreatitis is a curious one since each may be a complication of the other As a result, it may be difficult in any given case to determine which is the primary disorder

Escherichia coli and enterococci are the organisms most frequently recovered from infected bile ducts but a wide variety of other bacteria are capable of inducing acute cholangitis Most infections appear to be of the ascending type organisms gaining entrance to the common duct in the duodenum However hematogenous infections are known to occur and are of special importance in bacteremic diseases like typhoid and paratyphoid fever

It is doubtful that acute cholangitis occurs as a primary disease of the bile ducts In the curious syndrome known as *cholangitis lenta* it is alleged that the protracted *Streptococcus viridans* bacteremia which characterizes the disease is the result of a primary infection of a previously normal biliary tract However in most cases that have been investigated thoroughly an underlying biliary stone or tumor has been found

Often extrahepatic biliary obstruction is accompanied by an inflammatory reaction within the walls of the ducts and their supporting stroma in the liver even when there is no accompanying infection (p 145) Similar but less acute reactions are seen in chronic cholecystitis and a wide variety of nonbacterial hepatocellular diseases Often these are classified on an anatomic basis as forms of cholangitis However the term as used clinically implies a bacterial infection of the bile ducts often accompanied by a purulent exudate

Chills fever and jaundice are the outstanding *clinical features* in acute cholangitis Jaundice is not a constant finding, although an increase in serum bilirubin can almost always be demonstrated When present it may be due to (1) an underlying calculous or malignant biliary obstruction (2) increase of a previously asymptomatic partial occlusion by inflammatory edema or (3) hepatocellular injury as a result of the infection spreading to the parenchyma Often the liver enlarges and is painful but biliary colic is unusual except in those with an underlying common duct stone Anorexia nausea and vomiting are frequent complaints

If the cholangitis is secondary to an unrelieved partial biliary obstruction and especially a common duct stone chills and fever may recur at intervals of a few days to a few weeks a syndrome known as Charcot s intermittent biliary fever

Bacteremia liver abscess and pylephlebitis are the major complications Rarely chronic infection leads to contracture and occlusion of the extrahepatic bile ducts

Laboratory studies usually reveal marked leukocytosis hyperbilirubinemia bilirubinuria and a high serum alkaline phosphatase level Often the latter is present even in the absence of jaundice and this may be of considerable diagnostic value

Treatment depends on the underlying etiology but in general consists of surgical relief of biliary obstruction and the administration of antibiotics

VASCULAR DISEASE OF THE LIVER

Chronic Passive Congestion See p 1509

Occlusion of the Hepatic Veins (Budd Chiari Syndrome) The hepatic veins may be occluded by thrombus or tumor arising either locally or by extension from the inferior vena cava Rarely a congenital or acquired stricture is responsible

Hepatic vein thrombosis may be the result of (1) hepatic cirrhosis suppuration or malignancy (2) congenital stricture (3) polycythemia (4) crushing injury to the abdomen (5) local or generalized phlebitis (6) poisoning with senecio a weed found in South Africa or (7) thrombosis of the inferior vena cava secondary to intraabdominal suppuration malignancy or trauma Occlusion of the hepatic veins by tumor usually follows carcinomatous invasion of the vessels either directly from the liver or indirectly by way of the inferior vena cava from the kidney

The changes produced in the liver are those of severe congestion or cardiac cirrhosis (p 1509) depending on the duration of the disease

The *clinical course* is variable depending on the extent of the occlusion the rapidity with which it develops and the nature of the underlying etiology Occasionally the onset is abrupt with abdominal pain, vomiting progressive enlargement and tenderness of the liver and rapid accumulation of ascites Jaundice is an inconstant finding and when present is mild Patients with an acute and complete occlusion may go on to shock and die within a few days Others may survive for months or even years In the more chronic form of the disease ascites hepatomegaly and signs of portal hypertension predominate Ultimately the patient dies of hepato-

cellular failure mesenteric thrombosis hemorrhage from esophageal varices or as a result of the underlying disease responsible for the thrombosis Signs of inferior vena caval obstruction may antedate or accompany those pointing to occlusion of the hepatic veins

Occasionally hepatic vein thrombosis is discovered as an incidental finding at autopsy in individuals who allegedly have had no symptoms Presumably incomplete occlusion recanalization of the thrombus and the development of a collateral circulation account for the absence of symptoms in such cases

The *laboratory findings* are very much like those in chronic passive congestion and cardiac cirrhosis

Occlusion of the Portal Vein Most occlusions of the portal vein are the result of thrombosis but a few are of congenital origin due either to anomalous development of the vein or to neonatal extension of the obliterative fibrotic process in the ductus venosus and umbilical vein to the portal vein Occasionally the portal vein is replaced by a mass of thin walled vessels a condition known as *cavernomatous transformation* When it occurs in young individuals it usually is regarded as a congenital anomaly resulting from failure of the portal vein to canalize normally However since recanalization of an obstructed portal vein and the development of centripetal collateral vessels produces a similar picture cavernomatous transformation of the portal vein may represent an acquired anomaly even in children

Usually *acute thrombosis* is a complication of suppurative pylephlebitis or of surgical manipulation of the portal vein during splenectomy or porta caval anastomosis Less commonly it occurs during the course of a prolonged febrile illness such as typhoid fever or following abdominal trauma *Chronic thrombosis* which is more common is seen in approximately 10 per cent of cirrhotic patients and may be a complication of polycythemia vera or of carcinomatous invasion of the vein from any of the structures that it drains

The principal *clinical manifestations* relate to the development of portal hypertension and congestion In addition there may be signs pointing to the underlying disease responsible for the thrombosis The liver is not affected by the thrombosis per se but may be involved as a result of other concomitant factors

In acute thrombosis the early signs include abdominal pain ileus vomiting and diarrhea Later there may be ascites and splenomegaly and if the thrombosis spreads to the tributaries of the portal vein gastrointestinal infarction may ensue resulting in hematemesis melena and peritonitis

The signs of chronic thrombosis are those of portal hypertension which have been discussed elsewhere (p 149) Often the occurrence of thrombosis is overlooked particularly in patients with an underlying cirrhosis The possibility of this complication should be considered whenever sudden ascites or hematemesis occurs in a previously well compensated case of cirrhosis

Acute Pylephlebitis Acute bacterial infections of the portal vein are always secondary to suppurative foci in tissues drained by its tributaries or to suppuration in contiguous structures As previously noted (p 1513) acute appendicitis and biliary tract infections are the most common causes

The portal vein and its intrahepatic radicles show an acute inflammatory reaction and not infrequently contain pus or thrombi Hepatic abscess peritonitis and septicemia are common complications

The *clinical features* resemble those of pyogenic hepatic abscess and include chills fever nausea and vomiting abdominal pain and enlargement and tenderness of the liver Jaundice is an inconstant finding and if present is usually mild Signs of hepatic abscess or acute portal vein thrombosis may complicate the picture

Recovery may follow antibiotic therapy and surgical drainage of septic foci but the mortality rate is still high in the suppurative type of pylephlebitis Portal thrombosis and hypertension may be important sequelae

Cruveilhier Baumgarten Syndrome The outstanding feature in this condition is a periumbilical or epigastric venous bruit often accompanied by a thrill and usually associated with dilatation of the abdominal veins especially around the umbilicus where they form a rosette of vessels known as a *caput medusae*

Originally it was believed that the syndrome was always due to a congenital anomaly characterized by patency of the umbilical vein hypoplasia of the portal vein and secondary atrophy of the liver However it is now known that the dilated vessels and bruit usually are due to a greatly increased venous collateral circulation reaching the abdominal wall by way of the falciform ligament as a result of an acquired portal hypertension Both the umbilical and paraumbilical veins may participate in this process The syndrome occurs most frequently *in cirrhosis but may be seen in any other form of* portal hypertension

To distinguish between the congenital type due to failure of the umbilical vein to close and the acquired type related to portal hypertension it is customary to designate the former as Cruveilhier Baumgarten *disease* and the latter as the Cruveilhier Baumgarten *syndrome* However some authorities believe that the condition is always the result of portal hypertension and that patency of the

umbilical vein in the congenital type is the result rather than the cause of the associated hypoplasia of the portal vein.

Table 130. CHEMICAL AGENTS AND DRUGS KNOWN TO PRODUCE HEPATITIS IN MAN

Agent	Mode of action		
	Toxipathic	Sensitization	Virus carrier
Industrial and plant poisons			
Carbon tetrachloride	+		
Chlorinated naphthalenes and diphenyls	+		
Mushroom poison (*Amanita phalloides*)	+		
Phosphorus	+		
Senecio (ragwort poison)	+		
Tetrachlorethane	+		
Toluene	±		
Trinitrotoluene	+		
Anesthetic agents			
Chloroform	+		
Divinyl ether	?		
Ether (diethyl ether)	±		
Tribromethanol (Avertin)	?

251 DISEASES OF THE GALLBLADDER AND BILE DUCTS

Franz J Ingelfinger

Symptomatology The outstanding symptoms of disorders affecting the extrahepatic biliary system are pain and jaundice Very common but less specific symptoms are *fever* chills and a variety of *digestive disturbances*

Pain As is true of digestive viscera in general the major cause of pain in the biliary tract is an abrupt increase in intramural tension Thus any process which suddenly tenses the wall of the gallbladder or bile ducts—whether spasm or obstruction by tone—may precipitate biliary tract pain usually known as *biliary colic* To the patient biliary colic is severe and disabling a grinding pain that builds up rapidly persists maximally for 10 to 40 min tapers off gradually over hours and then terminates in a residual soreness lasting a day or more Although produced by smooth muscle and given the name *colic* biliary colic is a relatively steady pain without the extreme fluctuations characteristic of colic arising in the intestine Biliary colic originating in the hepatic or common duct is located high in the midepigastrium initially but spreads as the attack develops to the right and straight through the body to an area bounded by the vertebral column and the inferior angle of the right scapula If the gallbladder or cystic duct is the source of trouble colic is felt predominantly in the right epigastrium and tends to radiate along the costal margin to the right scapula Variants however do occur and in one out of ten cases pain extends principally to the left upper or right lower abdominal quadrant Biliary colic is not intensified by moving about—in fact the patient is often restless—but lifting the right arm or taking a deep breath may hurt presumably because of reflex spasm of upper abdominal and lower intercostal muscles

Gradual stenosis of the biliary passages as opposed to sudden obstruction is relatively painless Under such conditions an increase in intramural tension apparently is prevented by progressive atony of the biliary tract and diminished hepatic secretion

Biliary tract pain can also be caused by inflammation Slower in onset and duller in character this pain is also more persistent than biliary colic Because the inflammatory process usually irritates nearby parietal peritoneum pain of this type often becomes quite sharply localized in the right hypochondrium but patients with a markedly distended gallbladder or inflammatory mass projecting down to the level of the umbilicus place the maximum distress correspondingly lower

Jaundice Obstruction of the hepatic or common bile ducts leads to jaundice with regurgitation of free bilirubin and bile salts into the blood The rate at which jaundice appears and its degree depend upon the nature of the obstruction and the function of the gallbladder In gradual obstruction of the common duct as by neoplasm for example biliary congestion is initially cushioned by the storing and concentrating functions of the gallbladder which becomes greatly enlarged and filled with a thick and viscid concentrate of bile Jaundice usually does not become noticeable until considerable dilatation of both the extra and intrahepatic biliary tract has taken place In spite of the dilated bile channels within the liver however marked hepatic enlargement rarely occurs on the basis of bile stasis alone at first because of the safety valve function of the gallbladder and later because hepatic secretion is increasingly inhibited in the face of progressive biliary stasis With prolonged biliary obstruction indeed resorption of pigment from the stagnant bile takes place and may leave a clear and mucoid residue in the common duct

The situation is vastly different when the gallbladder is nonfunctioning or absent Under these conditions an acute obstruction of the common duct as by stone can produce slight icterus and choluria within hours and prolonged obstruction may lead to considerable enlargement of the liver particularly if biliary stasis is complicated by chronic infection Enlargement of the gallbladder is on the contrary unlikely since the nonfunctioning gallbladder usually has lost its elasticity and cannot take up bile

Complete occlusion of the cystic duct has little effect on a gallbladder permanently scarred by fibrosis but if the viscus is elastic it enlarges progressively to form a huge cystlike mass hydrops of the gallbladder The contents of a hydropic gallbladder gradually become colorless and occasionally calcium salts precipitate to form a turbid fluid known as *milk of calcium bile*

Fever and Chills These symptoms result from a combination of two factors biliary stasis and some mechanism permitting infection of the biliary passages Either condition alone is not enough For example patients with free regurgitation of chyme into the biliary radicles of the liver because of surgical anastomosis of hepatic duct to duodenum do not have fever or chills if the stoma is widely

patent Biliary stasis without infection as is characteristic of cancer in the head of the pancreas is likewise insufficient to cause fever and chills When biliary stasis occurs as a complication of gallstones however or when ulcerating cancers in the area of the ampulla of Vater allow bacteria to enter the common duct cholangitis develops and the patient is shaken by intermittent agues (Charcot's intermittent hepatic fever) The chills probably represent bouts of transient bacteremia

Disorders of the Gastrointestinal Tract Common manifestations of biliary tract disease include nausea vomiting belching epigastric bloating flatulence and constipation With severe biliary pain or inflammation intestinal distention and obstipation may be sufficiently marked to mimic obstruction of the gut Diarrhea is rare but may occur if an inflammatory cholecystic mass irritates the contiguous colon

If an obstruction of the biliary channels prevents bile from entering the intestine the digestion and absorption of fats is impaired and 10 to 40 per cent of the fat intake may be lost in the feces Fat soluble vitamins are similarly lost but the adult patient with biliary obstruction tolerates the loss of vitamins A D and E without serious consequences Decreased absorption of vitamin K however may rapidly induce hypoprothrombinemia

Impaired function of the gallbladder unlike obstruction of the common duct does not affect intestinal digestion or absorption and symptoms such as belching bloating and regurgitation are caused not by indigestion but by reflex disorders of gastrointestinal motility Thus the epigastric lump which distresses some patients after a fatty meal is not fat intolerance in the sense of impaired digestion of fat it is fat intolerance characterized by abnormal gastroduodenal motor mechanisms Since there are many extrabiliary causes for deranged gastroduodenal motility the symptoms of indigestion are not specific for gallbladder disease A patient with postcibal epigastric distress may have gallbladder disease or more likely a functional disorder unrelated to the biliary tract

Bleeding The question is often asked whether or not gallstones and their complications can cause bleeding into the gastrointestinal tract A few case reports exist of biliary tract bleeding caused by stones eroding into the hepatic artery or a minor vessel but as a general rule gallstones if not complicated by hypoprothrombinemia do not cause clinically significant blood loss

Biliary Tract Radiology

Radiopaque gallstones may be observed by plain films of the right upper abdomen To opacify various portions of the biliary system iodinated organic compounds excreted by the liver are used In routine cholecystography the compound is given by mouth Some 12 hr later the gallbladder contains sufficient dye to render it radiopaque provided that (1) gastrointestinal motility and absorption are normal (2) hepatic function is normal (3) the biliary channels are free of obstruction and (4) the gallbladder takes up concentrates and stores bile A gallbladder well filled with radiopaque dye indicates a normal viscus If radiolucent stones are present they are silhouetted against the contrast medium but small stones may at times be obscured by the very density of the dye This error may be avoided to a great extent by taking pictures with the patient standing or by taking successive pictures after evacuation of the gallbladder has been stimulated by a fatty meal (Fig 191)

Failure to visualize the gallbladder suggests an abnormal viscus provided the first three of the four conditions listed above are fulfilled At times even a normal gallbladder may fail to take up concentrate or store the dye This however happens only sporadically if the gallbladder fails to fill in each of two attempts at cholecystography the likelihood of gallstones is 90 per cent Poor concentration of the dye or increased or decreased rate of gallbladder evacuation in response to a fatty meal has little diagnostic significance Because of the enterohepatic circulation indeed a gallbladder may contain dye for many days following cholecystography

The dyes used for oral cholecystography are not sufficiently radiopaque to outline the biliary passages before concentration by the gallbladder The development of compounds (sodium iodipamide marketed as Biligrafin or Cholografin) which contain 65 per cent by weight of iodine and which are excreted by the liver (and in part by the kidney) within 5 to 50 min of their intravenous injection has permitted moderately satisfactory visualization of the larger biliary channels independent of gallbladder function Intravenous cholangiography is thus used to study patients whose gallbladders have been removed or are nonfunctioning because of disease A radiolucent stone in the common duct may at times be outlined by this procedure more often the partial obstruction produced by various choledochal lesions causes widening of the common duct (usual diameter less than 10 mm diameter over 15 mm definitely abnormal but magnification by x ray technique must be taken into account) and imparts a blunted dilated appearance to the intrahepatic radicles Like oral cholecystography intravenous cholangiography is unsuccessful in the face of hepatic disease or advanced biliary obstruction Failure to produce visualization with either procedure therefore has no diagnostic significance in a jaundiced patient On the other hand visualization of either the gallbladder or the bile ducts is at times possible in

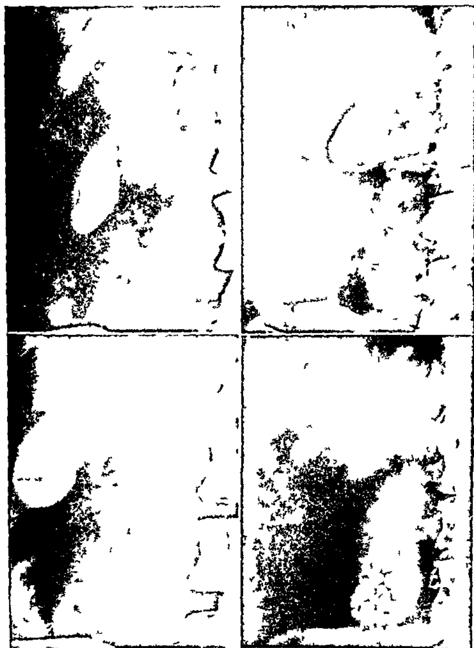

FIG 191 Results of cholecystography (*Upper left*) Normal gallbladder The concentrated radiopaque dye outlines the gallbladder and cystic hepatic and common ducts The dye appears in the ducts because this picture was taken after gallbladder evacuation had been stimulated by a fatty meal (*Upper right*) Cholelithiasis Nonopaque stones of varying sizes are shown as negative shadows within a gallbladder outlined by concentrated dye (*Lower left*) Cholelithiasis Numerous small stones are grouped in a layer near the bottom of the gallbladder This picture was taken with the patient standing Small stones such as these are dispersed when the patient is in a horizontal position and may be difficult to see (*Lower right*) Cholelithiasis Multiple radiopaque stones in a gallbladder with impaired concentrating ability

patent Biliary stasis without infection as is characteristic of cancer in the head of the pancreas is likewise insufficient to cause fever and chills When biliary stasis occurs as a complication of gallstones however or when ulcerating cancers in the area of the ampulla of Vater allow bacteria to enter the common duct cholangitis develops and the patient is shaken by intermittent agues (Charcot's intermittent hepatic fever) The chills probably represent bouts of transient bacteremia

Disorders of the Gastrointestinal Tract Common manifestations of biliary tract disease include nausea vomiting belching epigastric bloating flatulence and constipation With severe biliary pain or inflammation intestinal distention and obstipation may be sufficiently marked to mimic obstruction of the gut Diarrhea is rare but may occur if an inflammatory cholecystic mass irritates the contiguous colon

If an obstruction of the biliary channels prevents bile from entering the intestine the digestion and absorption of fats is impaired and 10 to 40 per cent of the fat intake may be lost in the feces Fat soluble vitamins are similarly lost but the adult patient with biliary obstruction tolerates the loss of vitamins A D and E without serious consequences Decreased absorption of vitamin K however may rapidly induce hypoprothrombinemia

Impaired function of the gallbladder unlike obstruction of the common duct does not affect intestinal digestion or absorption and symptoms such as belching bloating and regurgitation are caused not by indigestion but by reflex disorders of gastrointestinal motility Thus the epigastric lump which distresses some patients after a fatty meal is not fat intolerance in the sense of impaired digestion of fat it is fat intolerance characterized by abnormal gastroduodenal motor mechanisms Since there are many extrabiliary causes for deranged gastroduodenal motility the symptoms of indigestion are not specific for gallbladder disease A patient with postcibal epigastric distress may have gallbladder disease or more likely a functional disorder unrelated to the biliary tract

Bleeding The question is often asked whether or not gallstones and their complications can cause bleeding into the gastrointestinal tract A few case reports exist of biliary tract bleeding caused by stones eroding into the hepatic artery or a minor vessel but as a general rule gallstones if not complicated by hypoprothrombinemia do not cause clinically significant blood loss

Biliary Tract Radiology

Radiopaque gallstones may be observed by plain films of the right upper abdomen To opacify various portions of the biliary system iodinated organic compounds excreted by the liver are used In routine cholecystography the compound is given by mouth Some 12 hr later the gallbladder contains sufficient dye to render it radiopaque provided that (1) gastrointestinal motility and absorption are normal (2) hepatic function is normal (3) the biliary channels are free of obstruction and (4) the gallbladder takes up concentrates and stores bile A gallbladder well filled with radiopaque dye indicates a normal viscus If radiolucent stones are present they are silhouetted against the contrast medium but small stones may at times be obscured by the very density of the dye This error may be avoided to a great extent by taking pictures with the patient standing or by taking successive pictures after evacuation of the gallbladder has been stimulated by a fatty meal (Fig 191)

Failure to visualize the gallbladder suggests an abnormal viscus provided the first three of the four conditions listed above are fulfilled At times even a normal gallbladder may fail to take up concentrate or store the dye This however happens only sporadically if the gallbladder fails to fill in each of two attempts at cholecystography the likelihood of gallstones is 90 per cent Poor concentration of the dye or increased or decreased rate of gallbladder evacuation in response to a fatty meal has little diagnostic significance Because of the enterohepatic circulation indeed a gallbladder may contain dye for many days following cholecystography

The dyes used for oral cholecystography are not sufficiently radiopaque to outline the biliary passages before concentration by the gallbladder The development of compounds (sodium iodipamide marketed as Biligrafin or Cholografin) which contain 65 per cent by weight of iodine and which are excreted by the liver (and in part by the kidney) within 5 to 50 min of their intravenous injection has permitted moderately satisfactory visualization of the larger biliary channels independent of gallbladder function Intravenous cholangiography is thus used to study patients whose gallbladders have been removed or are nonfunctioning because of disease A radiolucent stone in the common duct may at times be outlined by this procedure more often the partial obstruction produced by various choledochal lesions causes widening of the common duct (usual diameter less than 10 mm diameter over 15 mm definitely abnormal but magnification by x ray technique must be taken into account) and imparts a blunted dilated appearance to the intrahepatic radicles Like oral cholecystography intravenous cholangiography is unsuccessful in the face of hepatic disease or advanced biliary obstruction Failure to produce visualization with either procedure therefore has no diagnostic significance in a jaundiced patient On the other hand visualization of either the gallbladder or the bile ducts is at times possible in

las from the biliary tract to adjoining viscera and gallstone ileus In addition gallstones appear to predispose the gallbladder to cancer Although the likelihood of these complications is greatest in those who develop gallstones at an early age have many small stones or suffer repeatedly from biliary colic any gallstone including so called silent stones (i e asymptomatic stones discovered accidentally by x ray or at operation) must be regarded as a potential source of trouble

Patients with gallstones and one or more attacks of biliary colic should be treated by cholecystectomy there is no medical means of cure and the probability of further colics and worse complications is great Patients with stones who suffer merely from indigestion" also deserve to have the gallbladder removed but the complaints may not be alleviated completely because their relation to the gallstones may be merely coincidental Finally a middle aged woman with a "silent" stone faces the following choice

1 Do nothing In this case the chances are approximately even that she will develop symptoms warranting cholecystectomy later Furthermore because she faces the risks of serious complications surgical fatality and cancer of the gallbladder the chances are about six out of a hundred that the silent gallstone eventually will cause her death

2 Immediate elective cholecystectomy The mortality risk varies widely but it probably averages about 1 per cent throughout the country In addition there is a 0 5 per cent risk of a surgical accident leading to stricture of the common duct a crippling and potentially fatal complication

Most surgeons pointing to the 4 1 ratio of mortality risks between these alternatives recommend immediate cholecystectomy These statistics however give only a two dimensional picture The 1 5 per cent risk is immediate and threatens a woman just beyond middle age The 6 per cent risk is usually incurred when the patient is sixty five to seventy five years old an age when her life expectancy is threatened by many disorders In other words in terms of patient *years* nothing is gained by elective cholecystectomy and it appears reasonable to follow the patient with silent stone and to recommend surgery if and when the first biliary colic takes place

ACUTE CHOLECYSTITIS

Acute inflammation of the gallbladder is associated with gallstones nine times out of ten The part played by biliary calculi in precipitating acute cholecystitis is not clear but in some cases sudden occlusion of the cystic duct by a gallstone produces biliary stasis and thus promotes an eruptive growth of the few bacteria that indolently inhabit many calculous gallbladders In nearly half the cases however bile removed from an acutely inflamed gallbladder contains neither bacteria nor pus the evidence for a primary bacterial infection is not good To explain these cases it has been suggested that a stone in the cystic duct causes enough spasm and edema to compromise the nearby cystic artery with resultant ischemic damage to the gall bladder wall Acute cholecystitis has also been attributed to chemical irritants in the bile and in the case of noncalculous varieties to bacterial infection reaching the gallbladder by vascular or lymphatic routes

Symptoms Upper abdominal pain and fever are the outstanding symptoms The pain either may begin gradually or may explode with biliary colic thereafter it settles as a chronic but severe distress in the right upper abdomen Ten per cent of cases however usually comprising those of advanced age suffer relatively little pain Nearly all patients have fever not necessarily striking but often spiking to 101 F at least once in 24 hr Chills may precede the febrile peaks Nausea and vomiting are common but clinically perceptible jaundice appears in no more than 25 per cent of patients If icterus is severe an associated choledocholithiasis may be responsible milder and more transient bouts of jaundice can probably be ascribed to spasm edema or inflammation of the ducts draining the liver

Signs In addition to fever local signs ranging from slight muscular guarding and sensitivity on fist percussion to acute tenderness and boardlike spasm are found almost invariably in the right upper abdomen A tender vague mass comprising the swollen gallbladder and adherent omentum is palpable in roughly half the cases

Laboratory and X ray A quite consistent finding is polymorphonuclear leukocytosis ranging between 10 000 and 20 000 The results of other blood and urine tests are not remarkable except for the evidences of regurgitation jaundice in the icteric cases Bromsulphalein retention and increased serum alkaline phosphatase may be noted even in the absence of bilirubinemia X rays may show radiopaque gall stones and oral cholecystography usually reveals nonfilling of the gallbladder

Diagnosis The differential diagnosis includes coronary pleural and pulmonary diseases right sided heart failure perforated peptic ulcer pancreatitis mesenteric occlusion appendicitis acute salpingitis pyelitis intestinal obstruction and in jaundiced cases liver disease hemolytic crises and malignancy affecting the extrahepatic biliary system These conditions are differentiated rather easily from a typical case of acute cholecystitis particularly if clinical judgment can be supported by x rays electrocardiograms and appropriate examinations of blood and urine The atypical rela

patients with bilirubinemia up to 5 mg per 100 ml

Direct cholangiography consists of injecting an iodinated water or oil soluble medium into the common duct either at the time of surgery or subsequently while a t tube is maintained in the common duct In intact patients those experienced in the techniques can inject radiopaque substances into the biliary passages especially the gallbladder by means of a needle percutaneously inserted and guided once in the abdomen under peritoneoscopic control A more hazardous procedure is puncture of the liver with a percutaneously inserted needle that is advanced until bile is aspirated at this point the radiopaque dye is injected These last two techniques are indicated it is obvious only in jaundiced patients presenting difficult problems in differential diagnosis and not considered candidates for exploratory laparotomy

GALLSTONES

At the age of thirty a few women and a rare man have gallstones by the time they die 25 per cent of women and 10 per cent of men are so afflicted Why or how these stones form is still unknown In some instances as in the case of pigment (bilirubin) stones found in patients with chronic hemolytic anemia the high concentration of bilirubin in the bile may lead to the precipitation of pigment Similarly a postulated but unproved abnormality in the biliary excretion of lipids may explain why cholesterol stones are alleged to be more common in multiparous women in diabetic patients and in the obese Finally it is possible that changes in the wall of the gallbladder may disrupt the physicochemical equilibrium which keeps the biliary constituents in solution In hamsters a low fat diet deficient in vitamin A appears *to cause gallstone formation*

A patient may have one gallstone or he may have over 200 Multiple stones are usually small and faceted sometimes they occur in groups of several sizes as if produced in successive crops Larger stones commonly one to three in number tend to be round or elliptical Pure pigment or pure cholesterol stones are rare usually both substances make up a gallstone and approximately *50 per cent of stones contain sufficient calcium to* make them radiopaque

Symptoms and Signs Half the people with gallstones *have no biliary symptoms The other half* suffer distress ranging from mild postprandial belching and bloating to full blown attacks of biliary colic The episodes of colic occur intermittently each attack presumably representing the reaction of the biliary tract as a stone passes through the common duct or is wedged into the entrance of the cystic duct. As might be expected therefore stimulation of the gallbladder by a fatty meal may precipitate biliary colic but many an attack seizes the patient in the middle of the night without any obvious dietary reason At the *height of the colic* nausea vomiting and difficulty in taking a deep breath are frequent but not invariable complaints *Tenderness and spasm in the right upper abdomen* are present when pain is maximal but thereafter recede rapidly Residual sensitivity to fist percussion over the ribs may however persist for several days Between attacks the patient may feel in the best of health

Diagnosis Characteristic biliary colic typical in location and radiation is usually recognized without difficulty Though intense it is less disabling and prostrating than the pains of intestinal perforation mesenteric occlusion severe myocardial infarction or hemorrhagic pancreatitis Less severe forms of myocardial infarction or pancreatitis may however cause pain not easily distinguished from biliary colic As a rule biliary colic is briefer than the pain of pleurisy but lasts much longer than each fluctuating wave of intestinal colic Both biliary colic and peptic ulcer pain may occur during the night but biliary colic tends to strike in irregular and isolated attacks whereas the pain of severe peptic ulcer returns regularly night after night

Although biliary colic can often be recognized clinically roentgenologic examination (see Biliary Tract Radiology above) and on occasion duodenal drainage are indicated to establish the diagnosis Normal or technically unsatisfactory cholecystographic results in patients suffering from biliary colic should be supplemented by microscopic examination of bile obtained by duodenal drainage If cholesterol crystals are found in a nonicteric patient the chances are 80 per cent that gallstones are present if calcium bilirubinate 50 per cent *and if both substances are identified 95 per cent* It is thus possible to diagnose gallstones even in the absence of clear cut x ray findings provided that the patient has biliary colic and either (1) nonfilling of the gallbladder on two cholecystograms or (2) cholesterol crystals in the duodenal contents Similar findings by x ray and duodenal drainage in patients suffering from no more than indigestion" must be interpreted more cautiously but may be *considered as good if not indisputable evidence* of gallstones In a jaundiced case x ray techniques are often not helpful and duodenal drainage may *occasionally be misleading* because prolonged biliary stasis of whatever cause may lead to precipitation of cholesterol or more often of bilirubinate pigment

Course and Indications for Surgical Treatment The possible complications of gall tones are many acute and chronic cholecystitis choledocholithiasis cholangitis hepatic abscesses biliary cirrhosis fistu

the gallbladder and become arrested as they pass from gallbladder to duodenum but under some conditions biliary "mud" (precipitated bile pigment) and even larger concretions form in the hepatic and common ducts It is therefore possible that stones found in the common duct of a patient who previously had a cholecystectomy were deposited *de novo* but it is more likely that the stones were already in the biliary channels at the time of surgery but escaped detection

Symptoms and Signs Gallstones in the common duct cause biliary colic jaundice fever and chills but the pattern of these symptoms is variable A stone rapidly passed from gallbladder to duodenum may prostrate the patient with colic but the attack is brief afebrile and jaundice if present at all is light and evanescent Two out of every five patients with common duct stones removed at surgery have had no evidence of jaundice If stones pass more slowly or become lodged in the common duct biliary colic may be accompanied by chills and fever and is usually followed by a definite wave of jaundice with dark urine and light stools Nausea and vomiting are more prominent than with colic originating in the gallbladder Within 24 to 48 hr many attacks subside and the patient in spite of the continued presence of stones in the duct is quite well until movement of the stones spasm or inflammatory edema precipitates the next bout Though choledocholithiasis may thus be silent between attacks both extra and intrahepatic biliary passages are exposed to progressive dilatation and to smoldering infection by such organisms as *E cherichia coli Aerobacter aerogenes* and *Streptococcus fecalis*

The biliary obstruction caused by choledochal stones is not always transient Some attacks of colic are followed by persistent jaundice which may be constant or may fluctuate as the stones in the common duct shift position or as the inflammatory reaction waxes and wanes During this period deep discomfort in the right hypochondrium gradually replaces the initial colicky pains presumably because choledochal motility becomes fatigued in the face of continuing obstruction and inflammation In some patients with chronic distention and infection of the choledochal wall pain is never prominent and about 5 per cent of patients chronically jaundiced because of choledocholithiasis have what is called "painless jaundice" Fever and chills indicate that an ascending cholangitis is flourishing in the obstructed biliary passages and give warning that multiple hepatic abscesses or pylephlebitis may ensue if biliary stasis is unrelieved Other symptoms are anorexia meteorism constipation and pruritus

On physical examination tenderness and some muscular guarding are usually found in the right hypochondrium In chronically jaundiced cases the liver is enlarged 1 to 4 cm below the costal margin because of biliary stasis ascending cholangitis or both The skin is often excoriated and may show the purpuric manifestation of hypoprothrombinemia

Diagnosis When the whole clinical triad of biliary colic jaundice and spiking fever characterizes choledocholithiasis differential diagnosis from the other major causes of persistent jaundice i e liver disease and neoplastic biliary obstruction, is not difficult By contrast, jaundiced cases with little pain or fever are knotty diagnostic problems In these a past history of coliclike pain or a shaking chill points to choledocholithiasis Itching and failure to palpate the gallbladder should also characterize the jaundice of choledocholithiasis but often are relatively unreliable guides Splenomegaly argues against calculous biliary obstruction as does a history of colicless jaundice appearing after exposure to chlorpromazine or other drugs producing intrahepatic but cholestatic jaundice Intravenous cholangiography (see Biliary Tract Radiology above) has proved a great advance in establishing or excluding the diagnosis of common duct stones in patients who have biliary colic after cholecystectomy Other findings that suggest choledocholithiasis are leukocytosis bilirubinemia, bilirubinuria or increased amylase values in blood or urine samples taken within 3 to 12 hr of an attack of colic The diagnosis of choledocholithiasis is also supported by the discovery of abnormal biliary sediment on duodenal drainage and in jaundiced patients by a pattern of liver function and bile pigment tests indicative of a fluctuating regurgitation jaundice In the face of persistent cholangitis however flocculation tests may yield increasingly positive values

GALLSTONE ILEUS

Fistulous tracts formed by gallstones eroding through a chronically diseased gallbladder or common duct may enter any adjoining viscus but by far the most common route leads into the duodenum Large stones "hen s egg" size are most apt to be responsible and, strangely enough stones like this may erode into the gut without producing acute symptoms Hours to days later however an escaped gallstone sometimes enlarged by layers of inspissated intestinal material, may suddenly cause gallstone ileus i e it may acutely obstruct the distal ileum or very rarely the sigmoid Gallstone ileus accounts for only 1 to 2 per cent of all small bowel obstructions but should be suspected whenever an elderly woman who has had biliary symptoms for years suddenly experiences ileal obstruction The suspicion is changed to certainty if x rays show gas shadows outlining the biliary passages

tively painless case however may go undiagnosed To avoid this error any elderly patient with unexplained fever and leukocytosis should be suspected of biliary tract disease and extra care is warranted in examining the right upper abdomen for slight guarding minimal tenderness or a vague mass Sometimes a difficult diagnostic problem is presented by acute colonic obstruction which may closely simulate acute cholecystitis particularly if the responsible lesion is an ulcerated cancer near the hepatic flexure Although many cases of cholecystitis are nonicteric early and repeated examinations of blood and urine for even fleeting signs of jaundice are invaluable in the correct interpretation of acute abdominal disorders

Course Many attacks of acute cholecystitis subside within 1 to 4 days but in some 40 per cent of cases the process either does not abate or is progressive It is then that the danger of empyema gangrene or perforation of the gallbladder becomes acute Other threatening complications are cholangitis liver abscesses pancreatitis and pylephlebitis An occasional sequel of acute cholecystitis is erosion of the damaged gallbladder wall by a gallstone which thereafter may continue to lie outside the gallbladder but in 90 per cent of these cases escapes into the gastrointestinal tract by means of a fistula between the gallbladder and duodenum

CHRONIC CHOLECYSTITIS

Two types of chronic cholecystitis must be distinguished that which is clinically a bona fide entity and that which is not The bona fide variety presents the symptoms of acute cholecystitis in dilute and chronic form These include upper abdominal distress ranging from epigastric pressure to biliary colic indolent bouts of fever intermittent mild jaundice and various digestive complaints The right hypochondrium is often tender and almost invariably sensitive to fist percussion Cholecystography reveals nonfilling of the gallbladder In the vast majority of cases with these clinical and radiologic findings the pathologist finds a thick walled contracted gallbladder containing stones Rarely however no stones are found Under such circumstances the origin of the chronic inflammatory process is obscure Some cases may be the residuals of an acute hematogenous cholecystitis in other instances it is probable that stones were present initially but were then passed via the bile ducts or fistulous communications into the intestinal tract Bona fide chronic cholecystitis with the clinical and radiologic criteria here defined warrants cholecystectomy

The bogus variety of chronic cholecystitis is a straw man conveniently erected to explain functional digestive complaints and waiting to be felled by useless operation The patient usually has a large variety of digestive and systemic complaints but belching bloating and epigastric pressure after meals are predominant Fat intolerance in the sense that these symptoms are aggravated by a fatty meal is typical Tenderness may be elicited in many spots but objective abnormalities on physical examination are nil On cholecystography the gallbladder is outlined and shows no stones but the concentration of the dye or its evacuation in response to a fatty meal may not satisfy the radiologist

Patients with this clinical picture have been and are labeled as having chronic cholecystitis on the grounds that improper cholecystic function literally causes indigestion with deficient exposure of chyme to bile that variations in the concentration and evacuation of cholecystographic dyes provide a satisfactory index of gallbladder morphology and function and that chronic inflammatory and degenerative changes in the gallbladder wall furnish substantial evidence that the viscus causes clinical symptoms Actually patients with alleged chronic cholecystitis have no demonstrable digestive or absorptive defect the concentration and evacuation of gallbladder dyes are variable phenomena and in very few fields is correlation between structural change and clinical symptomatology so poor as in disorders of the gallbladder Many an oldster has pathologic evidence of advanced cholecystitis but never a biliary symptom and conversely the gallbladder affected by acute cholecystitis may reveal few of the pathologic changes usually expected of inflammatory disease The "strawberry gallbladder with its prominent mucosal and submucosal deposits of cholesterol is another entity which is striking pathologically but of nebulous significance clinically

Perhaps the best evidence that this variety of noncalculous chronic cholecystitis is not a real clinical entity is found in its treatment Those who treat the condition medically advise antispasmodics antacids laxatives rest and sedatives for the insomnia of which a majority of these patients complain measures that are usually marshaled to treat functional disorders of the alimentary tract Those who go further and remove an allegedly poorly functioning but stoneless gallbladder account for many of the failures of cholecystectomy Since the gallbladder is not the cause of the symptoms the patient can hardly be expected to benefit from its removal

CHOLEDOCHOLITHIASIS

Gallstones are found in the common duct in one out of every seven patients operated on for biliary tract symptoms Most of these stones originate in

ford relief but their effect is only temporary Methyltestosterone 25 mg daily has been used to control the itching of regurgitation jaundice Bile salts have been made unnecessary by the availability of fat soluble vitamins in water miscible form in fact since bile salts may increase pruritus their use is inadvisable

Dietotherapy From many points of view a diet low in fats (40 to 75 Gm per day) appears suitable for all types of biliary tract disorders For those with gallbladder stones one object of therapy is not to provoke movement of the stones into a position where they might produce symptoms Since the ingestion of fats is a stimulus for gallbladder motility the dietary restriction of fats appears rational, even though many colics and other complications of cholelithiasis have no clear cut relation to the size and composition of antecedent meals For those who suffer from belching epigastric pressure and bloating a diet relatively low in fats is also recommended partly on empirical grounds and partly because fats are particularly instrumental in affecting the gastroduodenal motor mechanisms that are responsible for many of the symptoms of "indigestion"

As far as the surgical treatment of biliary tract disorders is concerned the following principles pertain to most cases

1 If gallstones are to be removed the gallbladder is if possible removed as well Sometimes the condition of the patient or a technical difficulty precludes cholecystectomy and the surgeon must content himself with cholecystostomy to drain the gallbladder of stones fluid or pus The disadvantage of this procedure is that the gallbladder remains behind to serve as a further seat of inflammation and stone formation On the other hand removal of the gallbladder incurs no disability Except for some compensatory dilatation of the common duct the structure of the biliary channels remains unaltered and the digestion and absorption of fats are not impaired Cholecystectomy as far as the patient is concerned need not interfere with normal living and a normal diet

2 Every effort is made to free the common duct of calculi or crystals that might serve as a nucleus for further stones For this reason the common duct is explored not only in patients who have had obvious symptoms of choledocholithiasis but also in those who have a good probability of choledocholithiasis as indicated by a past history of jaundice the presence of many small stones in the gallbladder or the operative finding of choledochal dilatation The careful search for common duct stones often entails the meticulous probing and flushing of the duct After the common duct has been inspected and cleared of stones it is the usual practice to drain the duct by means of a t tube for several weeks During and after operation direct cholangiography is used to advantage to ensure that no stones remain

3 The acutely inflamed gallbladder is ideally removed at a time when technical difficulties are minimal but before perforation or gangrene develop Nearly all surgeons agree that these ideals are fulfilled if cholecystectomy is performed immediately in patients seen within 48 hr of the onset of symptoms but the management of patients seen later in the course of their disease is subject to sharp controversy Some operate as soon as the patient can be prepared for surgery Others prefer to wait 1 to 3 weeks until inflammatory reaction and tissue friability subside Surgeons in this group intervene only if increasing fever pain leukocytosis and general evidences of toxicity suggest impending necrosis or perforation of the gallbladder

4 In jaundiced patients with choledocholithiasis a waiting period is usually indicated before surgery is undertaken This gives the obstruction an opportunity to subside spontaneously or if jaundice persists time is available for carrying out the repeated tests often necessary to establish the correct diagnosis

BILIARY DYSKINESIA

Disorders of gastrointestinal motor function are generally accepted as adequate causes of abdominal pain The underlying mechanisms although not well understood are believed to consist of muscular spasms and lack of coordination between motor functions that normally are smoothly integrated Even more obscure are the nonorganic disorders that affect the extrahepatic biliary tract, but it is reasonable that pain may arise here as in the gut on the basis of spasm and incoordination.

The dynamics of the biliary tract are normally regulated by a coordinated inverse relationship between hepatic secretion cholecystic evacuation and choledochal tone on one hand and sphincteric mechanisms on the other This relationship however may be replaced under the influence of certain pharmacologic neurogenic or locally irritative stimuli by uncoordinated activity usually referred to as *biliary dyskinesia* The gallbladder for example may ineffectually attempt evacuation against a cystic duct tightly closed by spasm Alternatively a contracted sphincter of Oddi and duodenal musculature may oppose forces actively promoting bile flow In either case intraluminal pressure between the opposing forces is increased the wall of a hollow viscus is tensed and pain ensues

The archtype of biliary dyskinesia is provided by the spasmogenic effect of morphine on the duodenum and sphincter of Oddi To some extent this effect of opiates takes place in everyone but in

clear evidence of an abnormal communication between the biliary and enteric tracts

STRICTURE

One of the most distressing disorders of the biliary tract is chronic stricture of the hepatic or common duct Perhaps one tenth of such strictures are spontaneous in the sense that they appear mysteriously or are the direct results of choledocholithiasis In most cases however accidental injury of the common duct during gallbladder surgery is the cause Sometimes the surgeon recognizes that he has cut the duct and attempts repair more often he is unaware of the accident until the patient becomes jaundiced or develops an external biliary fistula some days after operation The exact incidence of such common duct injuries is unknown in experienced hands it is very rare but throughout the United States accidental injury of the common duct probably occurs in one out of every 200 cholecystectomies

Stricture whether spontaneous or surgically induced causes partial biliary obstruction usually complicated by chronic infection The biliary tree behind the stricture becomes progressively dilated its branches tortuous and damaged by varying degrees of cholangitis With virulent infection multiple hepatic abscesses may develop but the more common end result is biliary cirrhosis Clinically the patient exhibits a course slowly carrying him downhill over months to years Much of the time he suffers only from mild jaundice itching lassitude and digestive disorders but at irregular intervals he is suddenly seized by rigors and headache followed by sharp increases in jaundice These bouts probably are caused by transient exacerbations of the chronic cholangitis with bacteremia and increased biliary obstruction produced by the inflammatory reaction in the common duct

The only effective therapy is surgical correction of the partial obstruction sometimes with the creation of new biliary intestinal anastomoses This is surgery that requires a master but if repair is successful in the sense that bile flow is unimpeded not only is the patient symptomatically relieved but even advanced grades of biliary cirrhosis recede miraculously

TREATMENT OF GALLSTONES AND THEIR COMPLICATIONS

The only definitive treatment of a gallstone is its surgical removal Medical measures however are necessary to relieve pain to tide the patient over attacks and to prepare him for surgery For the relief of pain often the patient s first need meperidine (Demerol) is usually recommended on the premise that this narcotic analgesic unlike morphine *does not cause spasm of the sphincter of* Oddi Unfortunately this agent may not provide the necessary relief in which case an opiate may become mandatory The dramatic benefit which patients with biliary tract pain often obtain from morphine or one of its derivatives suggests that the harm done by morphine induced spasm of the sphincter of Oddi is of greater theoretical than real importance

During acute attacks of painful or inflammatory nature *nothing is given by mouth and meteorism* is forestalled by constant gastric suction Fluids and electrolytes are provided parenterally In patients with fever (i e those with acute cholecystitis choledocholithiasis with cholangitis stricture) antibiotics are indicated Although it is true that antibiotics will not appear in static bile dammed up behind an obstruction their dissemination by the blood tends to prevent the spread of infection and decreases the dangers of bacteremia Broad spectrum antibiotics are often used but the combination of parenteral penicillin (one to two million units per day) and streptomycin (1 0 to 2 0 Gm per day) appears preferable from the viewpoint of wide effectiveness and low toxicity

To prepare the patient for surgery deficiencies in fluid and electrolytes must be corrected transfusions must be given to debilitated or anemic patients and infection must be combated with antibiotics Parenteral infusions of glucose solution (100 Gm or more per day) are probably beneficial to the patient who cannot eat and ascorbic acid and factors of the vitamin B complex may help in a nonspecific way Of crucial importance is the parenteral administration of vitamin K preparations to any patient who is jaundiced or has had jaundice recently for the prothrombin resources of such patients may be unexpectedly low Formerly before preparation of this type was possible biliary tract surgery was sometimes followed by a mysterious syndrome called *liver death* an acutely fatal reaction *characterized by high fever jaundice* restless coma and renal failure This syndrome which probably comprised a number of disorders is rarely seen today presumably because biliary tract surgery is now aided by more accurate diagnosis preoperative correction of deficiencies better control of infection and improved anesthetic technique

When biliary obstruction is prolonged as in the case of certain strictures or neoplasms of the common duct the patient is given a low fat diet water soluble or water miscible preparations of vitamins K A D and E by mouth and sulfonamides or antibiotics as needed for the control of cholangitis One of the most distressing symptoms is apt to be itching which is only partially controlled by local applications Calcium gluconate injections may af

symptoms persist after operation for the obvious reason that removal of a noncalculous gallbladder falsely incriminated under the diagnosis of chronic cholecystitis cannot be expected to alter upper abdominal distress produced by an irritable colon or some other disorder of gastrointestinal function

CANCER OF THE GALLBLADDER

As far as the general population goes cancer of the gallbladder is a rare and unimportant disease For those who develop gallstones before the seventh decade however the picture is different for unless cholecystectomy is performed 3 per cent of this group will succumb to this cancer

The early symptoms of cholecystic cancer usually go unrecognized and are attributed to a benign biliary disorder particularly since two-thirds of the patients with this cancer give a history of biliary symptoms extending over years In any elderly patient with clinical or radiologic evidence of gallstones however the diagnosis may be suspected if pain becomes boring and persistent rather than acute and episodic and if weight loss occurs because of anorexia rather than because of voluntary restriction of food intake Moderate to severe jaundice usually stable or progressive is seen on admission in half the cases Because of associated infection of the biliary tract or because of tissue destruction within or by the tumor fever is common and chills not rare In 50 to 75 per cent of the cases a hard and tender mass is palpable in the right upper quadrant but this may be confused with inflammatory tumor of the gallbladder with biliary cirrhosis and with metastatic nodules in the liver

Cancer of the gallbladder usually spreads by direct invasion of the liver and the vital structures of the hepatic porta Its successful surgical extirpation consequently is well nigh impossible and 5 year cures are reportable rarities

CANCER OF THE BILE DUCTS

Adenocarcinoma may grow in any portion of the bile ducts occasionally in the right or left hepatic duct sometimes in the common duct close to the ampulla of Vater but most frequently near the junction of the hepatic and cystic ducts It is not a common cancer In men who appear to be more frequently affected than women it occurs about one fifth as often as pancreatic cancer The clinical manifestations are similar to those of cancer in the head of the pancreas but may be modified by superimposed infection or by elimination of cholecystic function Thus cancers situated at or above the junction of the cystic and hepatic ducts produce hepatomegaly rather than enlargement of the gallbladder (Table 128 Chap 249) Although resection of early cancer in the distal common duct is possible the prognosis is usually hopeless as the growth spreads and secondary infection as well as persistent biliary obstruction impair hepatic function With increased attempts to examine the duodenal contents for exfoliated neoplastic cells and with additional experience in newer methods of cholangiography earlier diagnosis of some of these growths may be possible

UNUSUAL CONDITIONS

Congenital abnormalities of the gallbladder include complete absence of the viscus anomalous structure such as double gallbladder and unusual position within the liver or the anterior abdominal wall The bile ducts are also subject to numerous congenital defects among which atresia and cystic dilatation are the most prominent

Cholecystitis due to *Salmonella* is rare where salmonellae infections are controlled but formerly typhoidal infection of the gallbladder was responsible for many typhoid carriers Very infrequent causes of biliary tract infection are tuberculosis syphilis actinomycosis and septic emboli The characteristic lesions of periarteritis nodosa are sometimes exceptionally prominent in the walls of the gallbladder

The biliary tract may be infested by *ascarids liver flukes* and *Echinococcus cysts* These parasites may cause biliary obstruction with cholangitis and jaundice A parasite found in the United States in about 0 5 per cent of patients examined by duodenal drainage is *Giardia lamblia* but the pathogenicity of this organism is questionable

With improved cholecystography *small polypoid masses* are discovered not infrequently in the gallbladder but their clinical significance is controversial Many of these polyps are merely mucosal prominences containing localized cholesterol deposits much more rarely true adenomatous growths occur In either case the lesion cannot be held responsible for symptoms That the adenomatous polyps progress to cancer is a vehement but unproved assertion used by those who insist on cholecystectomy whenever a polyp is discovered radiologically in the gallbladder

Traumatic Rupture of the Gallbladder with bile peritonitis occasionally is a serious complication of abdominal injuries

hypersensitive patients opiates induce intense nausea vomiting and a violent contraction of the duodenum and sphincter of Oddi with biliary colic A similar though less well documented dyskinetic mechanism may account for the biliary type of pain that sometimes occurs during migrainous attacks for neurogenic nausea is usually accompanied by considerable duodenal spasm Finally it may be postulated that biliary dyskinesia is caused by cholinergic or adrenergic imbalance by reflexes from other organs and by locally irritative foci such as cystic duct remnants following cholecystectomy or the scars of spontaneous or operative injury In continental Europe and South America biliary tract motor abnormalities are analyzed much more minutely and a host of syndromes have been proposed on the basis of hypotonia hypertonia and atony of various parts of the tract The evidence for these syndromes is unconvincing

Symptoms Signs Diagnosis and Treatment Clinically the pain tenderness nausea and vomiting of biliary dyskinesia closely mimic organic disease of the gallbladder and bile ducts but jaundice fever chills and leukocytosis do not occur For purposes of management the syndrome may be divided arbitrarily but conveniently into three types

In the first type biliary dyskinesia appears as part of a more general syndrome in which various autonomic phenomena may be prominent The patient a woman nine times out of ten usually has had a stoneless gallbladder removed Headache giddiness scotomas nausea or some other aura may *precede* the biliary colic (in organic biliary tract disease pain is usually the first symptom) sweating and pallor may accompany it and loose bowel movements may follow A careful history may reveal that the attack has been precipitated by the ingestion of a minute quantity of opiate as may be found in many analgesics or cough medicines If this clinical picture is accompanied by completely negative laboratory and radiologic studies particularly a normal intravenous cholangiogram the treatment is medical In essence it consists of (1) reassurance (2) avoidance of opiates in all forms and (3) a combination (admittedly shot gun in character) of sedatives and antispasmodics to be taken at the very first sign of the attack e g salicylates anticholinergics and barbiturates or tranquilizers are given in combination and maximal oral doses in an effort to abort the attack and put the patient to sleep Since this type of dyskinesia resembles migrainous episodes in some respects ergotamine or Cafergot 3 to 5 tablets by mouth may be tried Once the attack is well on its way the physician may be forced to give meperidine subcutaneously

The patient with the second type of biliary dyskinesia has had a cholecystectomy for gallstones but biliary colic has persisted or returned and no studies made *provide any explanation* Unlike the colic in type I the colics in type II are not associated with other phenomena The attack *may be* treated with the combination of salicylates anticholinergics and sedatives or nitrites may be used in an effort to relieve muscular spasm If such measures fail however surgical exploration appears justified since an organic cause for the pain may exist in this type of case in spite of the negative *findings* If no obvious cause is found at operation management is difficult if a t tube is inserted and the patient is maintained on constant common duct drainage no attacks develop as long as the tube is in place Once the tube is removed the colics return whether or not procedures such as dilatation or cutting of the *sphincter of Oddi have been* attempted

Type III is the rarest The patient usually female has a normally functioning gallbladder but intermittently its emptying appears to be prevented perhaps by cystic duct spasm Treatment is medical a low fat diet with the salicylate anticholinergic sedative combination being used for the intermittent attacks

POSTCHOLECYSTECTOMY SYNDROME

The term *postcholecystectomy syndrome* is often used in referring to real or alleged biliary symptoms which persist after cholecystectomy but which cannot be explained on the basis of residual or new biliary calculi It thus serves as a scrap basket term which comprises a number of conditions

1 Organic abnormalities of the bile ducts such as stricture fibrosis of the sphincter of Oddi cystic duct stump and tumors of nerve tissue A cystic stump remaining after cholecystectomy has become a more important entity since the advent of intravenous cholangiography Such stumps may enlarge and may serve as a site for new gallstone formation Some surgeons hold cystic stumps responsible for symptoms whether or not additional disorders are present but this view appears untenable because uncomplicated cystic duct stumps are seen as often in normal postcholecystectomy patients as in those complaining of symptoms

2 Chronic relapsing pancreatitis

3 Biliary dyskinesia The operative record in most of these cases shows that no stones were found at cholecystectomy and it may be assumed that biliary dyskinesia accounts for both pre and postoperative symptoms In a few cases however biliary dyskinesia appears to affect patients who underwent cholecystectomy because of the sound indication of cholelithiasis

4 Functional gastrointestinal disorders In this the largest group of postcholecystectomy syndromes

The taking of the history and the physical examination then are the primary and fundamental methods in diagnosis Where there is disagreement as to diagnosis it will often be discovered that the source of the difficulty is an uncertainty as to the significant items in the history or physical examination Repeated examination may be necessary in order to establish them beyond doubt This is why it is said that the second examination is the most helpful diagnostic method in a difficult case

Different disease processes may cause identical symptoms which is understandable from the fact that several diseases may involve the same parts of the nervous system For example a spastic paraplegia may result from spinal cord tumor syphilitic meningomyelitis or multiple sclerosis Or one disease may cause several different symptoms Despite the almost infinite number of possible combinations of symptoms and signs a few occur with greater frequency than others and these can be *recognized as symptom complexes or syndromes* The experienced clinical worker acquires the habit of attempting to categorize every clinical case by placing it under one or another syndrome In doing so he more or less determines the anatomic basis of the illness in question and then proceeds to a search for etiologic factors

The final diagnosis must state the locality of the disease as well as its nature and to be complete should express the degree of functional impairment as well Anatomic diagnosis has precedence over etiologic diagnosis To seek the cause of a disease without first ascertaining the part or parts of the nervous system which are affected would be analogous in internal medicine to attempting etiologic diagnosis without knowing whether the disease involved the lungs stomach or kidneys

The study of neurology should always proceed from the general to the specific The student must learn the identity and differential diagnosis of the common syndromes before the details of individual diseases It should be kept clearly in mind however that syndromes are not diseases but rather abstractions set up by clinical workers in order to facilitate the diagnosis of disease The inherent danger in the method is that it may inculcate a rigidity of thinking and keep one from conceiving of diseases in new relationships

TAKING THE HISTORY

Skill in taking a clear meaningful history of an illness *is the mark of an able clinician In fact this* faculty more than any other distinguishes the competent from the incompetent clinical worker The following three points about history taking in neurology deserve comment

1 Special care must be exercised to avoid suggesting to the patient the symptoms that one seeks The clinical interview is a bipersonal engagement and the conduct of the examiner has a great influence on the patient Psychiatrists have talked and written about this so much that the repetition may seem tedious but it is evident that many of the conflicting histories presented on ward rounds can be traced to leading questions that have suggested to the patient the symptoms that the examiner expects to find or to an unconscious distortion of the patient s story Errors and inconsistencies in recording the history are as often the fault of the physician as of the patient Here the practice of making bedside notes is particularly to be recommended Considerable experience may be necessary to keep a suggestible and highly circumstantial patient on the subject of his illness and of course discreet questions are always necessary to draw out certain important points

2 The mode of onset and the course of the illness *are of paramount importance Often the nature* of the disease process can be decided by these facts alone One must know how each symptom began and progressed from the onset of the illness to the present If the patient cannot supply this information it may be necessary to judge the course of the symptoms by what he was able to do at different times i e how far he could walk whether he could carry on his work etc or by changes in the clinical findings between successive examinations Following a case and allowing time for a disease to evolve a method relied upon by all astute physicians takes advantage of the latter procedure

3 Since neurologic diseases often derange the patient s mind it is necessary in every case to decide during the interview by assessment of the mental status and the circumstances under which symptoms occurred whether or not he is competent to give the story of his own illness If not the history must be obtained from an outside source such as a relative friend or employer The nature *of certain illnesses such as a convulsion obviously* precludes the patient s knowledge of all the details of that part of his illness In general students and some physicians as well tend to be careless in the estimation of the mental capacities of their patients An attempt is sometimes made to take a history from a patient who is feebleminded or so confused that he has no idea why he is in a doctor s office or a hospital or from one who could not possibly have been aware of the details of the illness

THE NEUROLOGIC EXAMINATION

The neurologic examination begins always with the history The manner in which the patient tells the story of his illness may betray lack of coherence

Section 7 The Nervous System

252 APPROACH TO THE PATIENT WHO HAS A NEUROLOGIC PROBLEM

Raymond D Adams

Neurology is often regarded as one of the most difficult and exacting specialties of medicine The student coming to the neurology clinic for the first time is already somewhat intimidated by the complexity of the nervous system through his brief contact with neuroanatomy neurophysiology and neuropathology and often has a defeatist attitude The ritual he then witnesses of putting the patient through a series of maneuvers designed to evoke certain mysterious signs named after famous neurologists or called by unpronounceable terms does not reassure him In fact it often appears to conceal the very intellectual processes by which neurologic diagnosis is attained Moreover he has no aptitude for the many special tests which are used such as the lumbar puncture and cerebrospinal fluid examination and the electroencephalographic pneumoencephalographic and arteriographic examinations and does not know how to interpret the results of such tests when they are given him Neurologic textbooks only confirm his fears as he reads the details of the countless rare diseases of the nervous system

THE CLINICAL METHOD

The writer believes that many of the students difficulties with neurology may be overcome by proper instruction in the basic principles of clinical medicine First and foremost he must know and acquire facility in the use of the *clinical method* Without a clear comprehension of this method he is virtually as helpless with a new problem as would be the botanist or chemist who attempted to do research without having learned the scientific method

The importance of the clinical method stands *out more clearly in the study of neurologic diseases* than in certain other fields of medicine but the following remarks nevertheless have universal application The solution of any clinical problem is reached by a series of inferences and deductions each an attempt to explain an item in the history of an illness or a physical finding Diagnosis is the mental act of selecting the one explanation most compatible with all the facts of clinical observation Probably no two minds function exactly alike in this process and indeed one physician may not reason the same way on two different clinical problems Yet an analysis of the clinical method used will show that it generally consists of an orderly series of steps as follows

1 The essential clinical data are secured by history and physical examination

2 Those clinical data which are considered relevant to the current problem are interpreted and *translated in terms* of anatomy and physiology Certain complexes of symptoms and signs are recognized as having a meaningful relationship This may be called *syndromic diagnosis*

3 These data enable the physician to determine *the anatomic localization that best explains these* findings This may be called the *anatomic diagnosis*

4 The course of the illness the associated medical findings and the accessory laboratory data are then evaluated

5 And finally the *etiologic diagnosis* is educed from these data and from the location of the disease process

The elicitation of accurate and reliable data concerning the disordered functioning of the nervous system is the first step in diagnosis If these data are incorrect the diagnosis will surely be erroneous

Attention speed of response ability to give relevant answers to simple questions and in general the capacity for sustained mental effort all lend themselves to straightforward observation Useful bedside tests of attention memory and clarity of thought are the repetition of a series of digits in forward or reverse order serial subtraction of 7s from 100 the recall of the names of three objects after an interval of 3 min and the solution of simple problems and riddles Other tests can be devised for the same purpose Often the examiner can obtain a better idea of the clearness of the patient s sensorium and the soundness of his intellect by giving him a few tests and noting the manner in which he deals with them than by relying on a crude score of a formal intelligence or achievement test (see Chap 36)

If there is any suggestion of aphasia a record of the patient s spontaneous speech should be made In addition accuracy in the naming of objects in the execution of spoken commands and the ability to read and write should also be noted (see Chap 39)

Testing the Cranial Nerves The function of the cranial nerves must be investigated more fully than in the previous examination procedure Tests of smell are carried out only if one suspects a lesion in the anterior fossa and then it usually suffices to determine whether odors are perceived in each nostril In every case of brain disease the visual fields *should be outlined by a perimeter* and scotomas sought on the Bjerrum screen The careful use of a small white test object in a confrontation test of the visual fields is a useful method and should suffice in cases of spinal cord and peripheral nerve disease It may at times however reveal or localize a scotoma more accurately than the use of the Bjerrum screen

Sensation over the face should be tested with a pin and wisp of cotton and the corneal reflexes should be tried Facial movements should be observed as the patient speaks and smiles for a slight weakness may be more evident then than during voluntary movement Audiograms and special tests of auditory recruitment and labyrinthine tests are needed if there is suspicion of disease of the eighth nerve The vocal cords should be inspected in cases of medullary disease especially when there is hoarseness Corneal and pharyngeal reflexes are usually of value only if there is a difference on the two sides bilateral absence of gag and corneal reflexes is seldom significant Inspection of the protruded tongue is helpful atrophy fibrillation weakness and instability of posture may be seen Deviation of the protruded tongue to one or the other side as a solitary finding may usually be disregarded Articulation and the pronunciation of words should be noted The jaw jerk and buccal and sucking reflexes should be elicited particularly if there is suspicion of dysphagia or dysarthria (see Chap 30)

Tests of Motor Function In the assessment of motor function the student must always be reminded that observations of the speed and strength of movements of muscle bulk and of tone and coordination are usually more informative than the tendon reflexes It is essential to have the limbs fully exposed and to watch the patient maintain the arms in the outstretched position to perform simple tasks such as touching first the examiner s finger and his own nose to make rapid alternating movements that necessitate sudden acceleration and deceleration and changes in direction and to do simple tasks such as buttoning clothes opening a safety pin or handling common tools Estimates of the strength of leg muscles with the patient in bed are often unreliable there may seem to be no weakness even though the patient cannot step up on a chair or arise from a squatting position Running the heel down the front of the other shin and alternately touching the examiner s finger with the toe then the opposite knee with the heel is the only test of coordination that can be carried out in bed The maintenance of both arms or both legs against gravity is a useful test the weak one tiring first soon begins to sag Also abnormalities of movement and posture and tremors may appear (see Chap 26)

Tests of Reflex Function A large variety of tests of reflex function have been devised There are 20 or 30 special tests that can be performed on the foot alone Most of them can be ignored for all practical purposes it is recommended that only the response to stroking the outer part of the sole or lateral surface of the foot be used If the plantar reflex is extensor the others are superfluous if it is equivocal or flexor in type the other tests cannot be taken as substitutes When in doubt as to the nature of the response an involuntary flexion of the leg at the hip knee and ankle after a series of pinpricks is a valuable confirmation of an extensor plantar reflex The Hoffmann reflex in the hand better called the finger jerk is merely a tendon reflex and is not equivalent to the Babinski sign The biceps triceps and supinator or radial periosteal reflexes the knee and ankle reflexes and the cutaneou abdominal and plantar reflexes permit an adequate sampling of reflex activity of the spinal cord

Testing of Sensory Function The testing of sensory function is undoubtedly the most difficult part of the neurologic examination If the findings are to be reliable it should be reserved for the end of the examination procedure and not prolonged for more than a few minutes Usually an explanation of the purpose of the test should be given yet too

or confusion in thinking defection of memory faultiness of judgment or difficulty in comprehending or in expressing ideas This is an essential part of the examination of every medical case and provides information as to the adequacy of cerebral function Usually this type of information can be obtained without embarrassment to the patient The physician should maintain the same objective attitude towards the verbal responses of his patient and the thoughts expressed as he does in auscultation of the chest A common error is to pass over inconsistencies in history and inaccuracies about dates and symptoms as being unimportant only to discover later that these are the major symptoms of the illness

The remainder of the neurologic examination should be performed as part of the general physical examination and not as a special procedure to be done later if indicated It should always be carried out in an orderly systematic manner proceeding from the examination of the cranial nerves to the upper extremities trunk and lower extremities in order to avoid omissions The cranial nerves can be tested along with the examination of the eyes ears nose and throat The arms should be examined after the cervical structures and before the heart and lungs and the legs before the pelvic and rectal examination Gait and station should be observed at some time during the procedure usually before or after the rest of the examination

The thoroughness of the examination of the nervous system must of necessity depend on the type of clinical problem presented by the patient To spend a half hour testing motor and sensory function in a patient seeking treatment for a sprained ankle is pointless and uneconomical Furthermore the procedure must be varied according to the condition of the patient If he is comatose obviously many tests cannot be done infants and small children and psychotic patients must be examined in special ways Some comments about the examination procedure in each of these clinical circumstances will follow

The Average Medical or Surgical Patient without Neurologic Symptoms Brevity is desirable in the neurologic examination but any test that is undertaken should be done well and recorded accurately on the patient s chart In the examination of the cranial nerves the pupil size reaction to light ocular movements visual acuity and auditory acuity (by question) movements of face jaw palate and tongue should be scrutinized Observing the bare outstretched arms for atrophy weakness tremor or abnormal movements inquiring about strength and subjective sensory disturbances and tapping the supinator biceps and triceps tendons to evoke reflexes are usually sufficient for the upper extremities The abdominal reflexes should be tested when the abdomen is examined Inspection of the legs as the feet toes and knees are actively flexed and extended elicitation of the knee and ankle jerks and stroking the lateral border of the foot for the plantar reflexes complete the essential part of the neurologic examination The only sensory tests that should be attempted are vibration and position in the fingers ankles and feet Coordination may be tested by watching the patient place his finger on the tip of his nose and run the heel up and down the front of his leg This entire procedure does not add more than 3 or 4 min to the physical examination The routine performance of these few simple tests may offer clues as to the presence of diseases of which the patient is not aware For example by finding Argyll Robertson pupils absent tendon reflexes and diminished vibratory and position sense in the legs the surgeon is alerted to the possibility of the gastric crises of tabes when there are no other symptoms of neurosyphilis

An accurate record of the results of these tests should be kept Even if the tests are negative and do not aid in understanding the present illness a neurologic disease developing later may be more accurately dated

Patients Who Present Symptoms of a Disease of the Nervous System Several monographs have been written on the neurologic examination of such patients For a full account of the methods the reader is referred to Denny Brown Monrad Krohn Wartenberg and DeJong each of whom approaches the subject from a special point of view A large number of tests have been devised and it is not proposed to review them Many are of doubtful value and should not be taught to students of neurology Merely to perform all these tests on any one patient would require several hours and probably the examiner would in many instances be none the wiser The danger in all clinical tests is that the student and physician may regard them as the inscrutable symbols of disease rather than manifestations of disordered functioning of the nervous system In general the tests which provide the most useful information are few in number and relatively simple The student should be taught to do these few tests well and to understand their meaning The entire examination procedure should never require more than 15 or 20 min because if it does the patience of both examiner and patient are likely to be exhausted and the results then become inaccurate

Testing of Cerebral Function Cerebral function is tested in detail only if there is reason to suspect some defect from the patient s behavior during the general examination Questions should then be directed towards determining orientation in time and place and insight into the current medical problem

Attention speed of response ability to give relevant answers to simple questions and in general the capacity for sustained mental effort all lend themselves to straightforward observation Useful bedside tests of attention memory and clarity of thought are the repetition of a series of digits in forward or reverse order serial subtraction of 7s from 100 the recall of the names of three objects after an interval of 3 min and the solution of simple problems and riddles Other tests can be devised for the same purpose Often the examiner can obtain a better idea of the clearness of the patient s sensorium and the soundness of his intellect by giving him a few tests and noting the manner in which he deals with them than by relying on a crude score of a formal intelligence or achievement test (see Chap 36)

If there is any suggestion of aphasia a record of the patient s spontaneous speech should be made In addition accuracy in the naming of objects in the execution of spoken commands and the ability to read and write should also be noted (see Chap 39)

Testing the Cranial Nerves The function of the cranial nerves must be investigated more fully than in the previous examination procedure Tests of smell are carried out only if one suspects a lesion in the anterior fossa and then it usually suffices to determine whether odors are perceived in each nostril In every case of brain disease the visual fields should be outlined by a perimeter and scotomas sought on the Bjerrum screen The careful use of a small white test object in a confrontation test of the visual fields is a useful method and should suffice in cases of spinal cord and peripheral nerve disease It may at times however reveal or localize a scotoma more accurately than the use of the Bjerrum screen

Tests of Motor Function In the assessment of motor function the student must always be reminded that observations of the speed and strength of movements of muscle bulk and of tone and coordination are usually more informative than the tendon reflexes It is essential to have the limbs fully exposed and to watch the patient maintain the arms in the outstretched position to perform simple tasks such as touching first the examiner s finger and his own nose to make rapid alternating movements that necessitate sudden acceleration and deceleration and changes in direction and to do simple tasks such as buttoning clothes opening a safety pin or handling common tools Estimates of the strength of leg muscles with the patient in bed are often unreliable there may seem to be no weakness even though the patient cannot step up on a chair or arise from a squatting position Running the heel down the front of the other shin and alternately touching the examiner s finger with the toe then the opposite knee with the heel is the only test of coordination that can be carried out in bed The maintenance of both arms or both legs against gravity is a useful test the weak one tiring first soon begins to sag Also abnormalities of movement and posture and tremors may appear (see Chap 26)

Tests of Reflex Function A large variety of tests of reflex function have been devised There are 20 or 30 special tests that can be performed on the foot alone Most of them can be ignored for all practical purposes it is recommended that only the response to stroking the outer part of the sole or lateral surface of the foot be used If the plantar reflex is extensor the others are superfluous if it is equivocal or flexor in type the other tests cannot be taken as substitutes When in doubt as to the nature of the response an involuntary flexion of the leg at the hip knee and ankle after a series of pinpricks is a valuable confirmation of an extensor or plantar reflex The Hoffmann reflex in the hand better called the finger jerk is merely a tendon reflex and is not equivalent to the Babinski sign The biceps triceps and supinator or radial periosteal reflexes the knee and ankle reflexes and the cutaneous abdominal and plantar reflexes permit an adequate sampling of reflex activity of the spinal cord

Testing of Sensory Function The testing of sensory function is undoubtedly the most difficult part of the neurologic examination If the findings are to be reliable it should be reserved for the end of the examination procedure and not prolonged for more than a few minutes Usually an explanation of the purpose of the test should be given yet too

much discussion of it with a meticulous intro spective patient *may encourage the reporting of* useless minor variations of stimulus intensity It is well to ask whether or not stimuli on opposite sides of the body feel the same not if they feel different If the patient is highly suggestible in which case sensory tests are unreliable differences that demand further investigation will not be reported

The skin surface of the body is large and it is not necessary to examine all areas A quick survey of the face neck arms trunk and legs with a pin takes only a few seconds One is of course usually seeking differences between the two sides of the body a level below which sensation is lost or a zone of relative or absolute anesthesia Regions of sensory deficit can then be tested more carefully and mapped out Hyperesthetic zones are usually not of much help in diagnosis and more often than not are the result of faulty technique nevertheless they may call attention in some patients to areas of peripheral sensory disturbance Variations in the sensory findings from one examination to an other reflect differences in technique of examination as well as inconsistency in the responses of the patient

Light touch pain temperature vibratory and position sense should be examined systematically in every neurologic case Stereognosis tactile locali zation two point discrimination and the recogni tion of numbers written on the skin afford the means of evaluating cutaneous perception If the patient is an unreliable witness only a few tests such as position and vibratory sense in the fingers and toes pinprick in hands trunk and feet and stereognostic sense in hands are worthwhile (see Chap 27)

Testing Gait and Stance No examination is com plete without seeing the patient on his feet and walking An ataxia of gait may be the only neuro logic abnormality as in certain cases of cerebellar tumor Or the stance posture and lack of certain highly automatic adaptive movements may be the most definite finding in an early case of paralysis agitans

The Comatose Patient Although subject to ob vious limitations examination of the stuporous or comatose patient may yield considerable informa tion concerning the function of the nervous system The special techniques involved have been pre sented in Chap 33 Coma and Related Disturbances of Consciousness

The demonstration of signs of focal brain disease or of meningeal irritation is of aid in the differential diagnosis of the diseases which cause coma As al ready pointed out three syndromes are discernible

1 Coma without meningitis (or changes in cerebrospinal fluid) or signs of focal lesions in one or the other hemisphere or brain stem This is usually due to drug intoxication or a metabolic dis ease such as diabetic acidosis uremia liver coma *hypoglycemia* Addison s disease etc

2 Coma with meningeal irritation and changes in cerebrospinal fluid but without signs of focal lesions of the brain Meningitis or subarachnoid hemorrhage is the usual cause

3 Coma with signs of a focal lesion of the brain with or without signs of meningeal irritation or changes in the cerebrospinal fluid This is usually due to a brain hemorrhage infarction tumor abscess encephalitis or epidural or subdural hema toma In any one of these syndromes a convulsion may cause a serious transitory derangement of con sciousness that confuses the clinical picture

The Psychiatric Patient One is compelled in the examination of psychiatric cases to rely less on the cooperation of the patient and to be unusually critical of his statements and opinions The de pressed patient for example may declare that his limbs are weak or useless when actually there is little or no diminution in muscular power or the psychopathic patient may feign paralysis The op posite is sometimes true—that the most psychotic patient may make accurate observations of his own *symptoms only to have them ignored because the* attending physician has been in the habit of disre garding his complaints

If the patient will speak and cooperate to the slightest degree much may be learned as to the functional integrity of different parts of the nervous system Aphasia can in nearly every instance be diagnosed by the manner in which the patient uses words in phrases and sentences or responds to spoken or written commands Often it is possible to determine whether there are hallucinations de fective memory or other symptoms of recognizable brain disease merely by watching and *listening to* the patient The visual fields can often be tested with fair accuracy by observing the patient s re sponse to a moving stimulus or threat in all four quadrants of the fields The tests of cranial nerve motor and reflex function in the legs outlined above for the examination of the stuporous and comatose patient can be carried out even better if minimal cooperation is obtained from the patient It must be remembered however that the neurologic ex amination is never complete unless the patient will speak and carry out the usual tests On numerous occasions mute patients judged to be schizophrenic have had some widespread cerebral disease such as hypoxic or hypoglycemic encephalopathy a brain tumor a vascular lesion or extensive de myelinative lesions

Infants and Small Children At an early age before a child has learned to speak or carry out spoken commands neurologic disease manifests it self almost exclusively as a disturbance of sensori motor reactions Many parts of the neurologic ex amination which are of value in testing nervous

function in adults are of little use in infants For example the tendon and plantar reflexes are seldom of much help The examination of the optic fundi rarely is of value except in amaurotic familial idiocy toxoplasmosis or tuberous sclerosis Sensory tests except response to painful stimulation are not worthwhile More can be learned by merely sitting at the bedside for a few minutes and observing the activity of the patient than by attempting special tests Within a few minutes the average infant who is awake will move every muscle in the body Rigidity or spasticity of the limbs or paralysis of a muscle or group of muscles is easily discovered by merely observing these motor performances and by manipulating the limbs

The neurologic examination of the infant and small child should always begin with careful inspection of the head and palpation of the anterior fontanel Peculiarities in the shape and size of the skull are often found with brain disease The head is unnaturally small in many cases of amentia with gross brain lesions and unilaterally small with hemiatrophy of the brain Premature closure of sutures which accounts for odd shapes of the skull is frequently associated with brain disease and developmental retardation And of course enlargement of the head may occur with hydrocephalus chronic subdural hematoma and rarely macrocephaly Retarded children who remain in one position because of a postural abnormality due to nervous disease may show flattening of the skull on one side A bony defect a tuft of hair or a peculiarity in the skin over neck and spine permit diagnosis of a cranium bifidum or spina bifida (see Chap 253)

Visual activity assumes particular importance after the first 2 or 3 weeks of life Conjugate movements of the eyes in fixating and following a visual stimulus develop early The coordination of hand and eye and alertness to a moving stimulus introduced in various parts of the visual field are normally acquired in the first 1 to 3 months Retardation in these activities suggests a specific visual defect or a general disturbance in nervous development Attentiveness and response to sounds also constitute a good test of sensorimotor organization and of adaptive behavior

The organization of motor activity in head control in grasping and reaching for objects in sitting crawling standing walking and vocalizing are reliable indices of the functional activity of the nervous system Social behavior may later be used in the same way as a sign of nervous organization These motor skills and adaptive and social behavior develop in an orderly sequence a timetable has been established by Gesell and other workers The developmental quotient a figure arrived at by comparing chronologic age with developmental age expresses the degree to which motor development is retarded Unless conditioned by psychologic factors a significant degree of retardation of development signifies a disease of the brain which may prove as time passes to be regressive stationary or progressive The subsequent course of the illness should distinguish these three classes of disease A progressive brain disease not only interferes with the normal processes of maturation but may cause an actual regression in behavior

Neurologic diseases in infancy may be extensive without causing obvious focal neurologic signs and it must be assumed that the functions of a large part of the cerebrum and basal ganglions are in abeyance during the early months of life Cerebellar ataxia and motor and sensory paralysis from cerebral lesions may not be recognizable at this time In fact seizures general motor inactivity lack of startle reaction opisthotonos and abnormal postures poor regulation of breathing and inability to suckle are the only dependable neurologic signs during the first days and weeks of life

The author has found the methods of examination outlined by Gesell and Amatruda and by Andre Thomas to be of far greater value in infants than those customarily employed by neurologists However the limitations of a clinical method that depends largely on assessment of the strictly motor aspects of behavior are obvious Experience in pediatric neurology dictates caution in prognosticating the potential mental capacities of an infant until there is a sufficient degree of maturation to permit the testing of the more specific sensorial and intellectual faculties of the mind

IMPORTANCE OF A WORKING KNOWLEDGE OF NEUROANATOMY AND NEUROPHYSIOLOGY

Once the technique of obtaining reliable clinical data is mastered the student may find himself handicapped in the interpretation of the findings by a lack of facility in neuroanatomy and neurophysiology These are highly complex subjects and to acquire a practical working knowledge of them is time consuming Fortunately these subjects are taught well in most schools and those principles which are immediately applicable to the clinical neurologic problem are not too difficult.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the cause of a clinical syndrome requires knowledge of an entirely different order One must be conversant with the clinical details and the course and natural history of the more common disease entities Many of these facts are simple and well known and can be found in any standard textbook on neurology For instance the distinguishing characteristic of vascular

much discussion of it with a meticulous intro spective patient may encourage the reporting of useless minor variations of stimulus intensity It is well to ask whether or not stimuli on opposite sides of the body feel the same not if they feel different If the patient is highly suggestible in which case sensory tests are unreliable differences that demand further investigation will not be reported

The skin surface of the body is large and it is not necessary to examine all areas A quick survey of the face neck arms trunk and legs with a pin takes only a few seconds One is of course usually seeking differences between the two sides of the body a level below which sensation is lost or a zone of relative or absolute anesthesia Regions of sensory deficit can then be tested more carefully and mapped out Hyperesthetic zones are usually not of much help in diagnosis and more often than not are the result of faulty technique nevertheless they may call attention in some patients to areas of peripheral sensory disturbance Variations in the sensory findings from one examination to an other reflect differences in technique of examination as well as inconsistency in the responses of the patient

Light touch pain temperature vibratory and position sense should be examined systematically in every neurologic case Stereognosis tactile locali zation two point discrimination and the recogni tion of numbers written on the skin afford the means of evaluating cutaneous perception If the patient is an unreliable witness only a few tests such as position and vibratory sense in the fingers and toes pinprick in hands trunk and feet and stereognostic sense in hands are worthwhile (see Chap 27)

Testing Gait and Stance No examination is com plete without seeing the patient on his feet and walking An ataxia of gait may be the only neuro logic abnormality as in certain cases of cerebellar tumor Or the stance posture and lack of certain highly automatic adaptive movements may be the most definite finding in an early case of paralysis agitans

The Comatose Patient Although subject to ob vious limitations examination of the stuporous or comatose patient may yield considerable informa tion concerning the function of the nervous system The special techniques involved have been pre sented in Chap 33 Coma and Related Disturbances of Consciousness

The demonstration of signs of focal brain disease or of meningeal irritation is of aid in the differential diagnosis of the diseases which cause coma As al ready pointed out three syndromes are discernible

1 Coma without meningitis (or changes in cerebrospinal fluid) or signs of focal lesions in one or the other hemisphere or brain stem This is usually due to drug intoxication or a metabolic dis ease such as diabetic acidosis uremia liver coma hypoglycemia Addison s disease etc

2 Coma with meningeal irritation and changes in cerebrospinal fluid but without signs of focal lesions of the brain Meningitis or subarachnoid hemorrhage is the usual cause

3 Coma with signs of a focal lesion of the brain with or without signs of meningeal irritation or changes in the cerebrospinal fluid This is usually due to a brain hemorrhage infarction tumor abscess encephalitis or epidural or subdural hema toma In any one of these syndromes a convulsion may cause a serious transitory derangement of con sciousness that confuses the clinical picture

The Psychiatric Patient One is compelled in the examination of psychiatric cases to rely less on the cooperation of the patient and to be unusually critical of his statements and opinions The de pressed patient for example may declare that his limbs are weak or useless when actually there is little or no diminution in muscular power or the psychopathic patient may feign paralysis The op posite is sometimes true—that the most psychotic patient may make accurate observations of his own symptoms only to have them ignored because the attending physician has been in the habit of disre garding his complaints

If the patient will speak and cooperate to the slightest degree much may be learned as to the functional integrity of different parts of the nervous system Aphasia can in nearly every instance be diagnosed by the manner in which the patient uses words in phrases and sentences or responds to spoken or written commands Often it is possible to determine whether there are hallucinations de fective memory or other symptoms of recognizable brain disease merely by watching and listening to the patient The visual fields can often be tested with fair accuracy by observing the patient s re sponse to a moving stimulus or threat in all four quadrants of the fields The tests of cranial nerve motor and reflex function in the legs outlined above for the examination of the stuporous and comatose patient can be carried out even better if minimal cooperation is obtained from the patient It must be remembered however that the neurologic ex amination is never complete unless the patient will speak and carry out the usual tests On numerous occasions mute patients judged to be schizophrenic have had some widespread cerebral disease such as hypoxic or hypoglycemic encephalopathy a brain tumor a vascular lesion or extensive de myelinative lesions

Infants and Small Children At an early age before a child has learned to speak or carry out spoken commands neurologic disease manifests it self almost exclusively as a disturbance of sensori motor reactions Many parts of the neurologic ex amination which are of value in testing nervous

Some of these conditions are manifest at birth others may be recognized only in late infancy and early childhood after some degree of maturation is attained Together these diseases comprise a large segment of pediatric neurology and to discuss them fully it would be necessary to touch upon the entire field of nervous disease in infancy and childhood However in a textbook of medicine limitations of space prevent the presentation of pediatric disease and for this reason only those conditions which permit long survival and are likely to come to the attention of the internist and general physician are considered

MAJOR PROBLEMS OF PEDIATRIC NEUROLOGY

The diseases included in this chapter differ from most of those acquired in late childhood adolescence and adult life in that they are likely to cause deformity of the skull spine and limbs delayed or abnormal motor and speech development or mental retardation The corollary of this axiom is that when any one of these abnormalities is observed in the adult there is a strong probability of a disease of the nervous system that had its onset before birth or during infancy or early childhood Understanding fully the significance of these three types of abnormality will enable the student or physician to deal effectively with the majority of patients who suffer from developmental abnormalities For this reason this chapter is devoted to an exposition of these topics In addition certain seizure problems peculiar to the pediatric age group deserve special consideration here

Malformations of the Cranium Spine and Limbs

A congenital abnormality may be defined as a structural defect in some tissue or organ of the body which is present at birth It may be gross or microscopic on the surface of the body or within it familial or sporadic hereditary or nonhereditary single or multiple (Warkany)

Estimates as to the incidence of congenital abnormalities of the nervous system vary substantially depending upon the definition adopted by the reporter and the time in life when the survey was made Malpas found a congenital malformation of the nervous system in approximately 1 per cent of 13 000 births and McIntosh and his associates give a figure of 1 3 per cent of total births 7 2 per cent of stillbirths 6 1 per cent of infants dying in the first days of life and 1 1 per cent of live births Malformations of the central nervous system are of importance in stillbirth and infantile mortality They cause 76 per cent of all fetal deaths prior to birth and 69 per cent of deaths in the first year of life according to Record and McKeown As was pointed out by Murphy the nervous system is involved in 60 per cent of all patients with a congenital malformation

General understanding of these malformations has been advanced by experimental teratology a branch of biology that seeks the causes of abnormalities of structural development In the progeny of animals possessing certain abnormal genes developmental abnormalities can be predicted in ratios that agree with established genetic laws Equally predictable results have been obtained by subjecting the embryo or fetus under controlled conditions to certain environmental stresses X ray hypoxia deficient diet viral infections and toxic substances have been shown to induce a variety of defects in the central nervous system depending on the stage of embryogenesis at which the noxious agent is applied to the pregnant animal These genetically and environmentally determined malformations serve as experimental models which can be investigated to great advantage

In human beings both genetic and environmental factors have been established in the production of congenital defects Neurofibromatosis (von Recklinghausen) encephalotrigeminal syndrome (Sturge Weber Dimitri) cerebelloretinal syndrome (Lindau and von Hippel) craniofacial dysostosis (Crouzon) optic atrophy (Leber) and craniostenosis with syndactylism (Apert) have a dominant pattern of inheritance the lipid storage diseases (Tay Sachs) and gargoylism (Hurler) phenylketonuria hepatolenticular degeneration (Wilson) Hallevorden Spatz disease and galactosemia are examples of recessive heredity Specific enzymes are found to be lacking in some of these diseases and are suspected of being absent in others Examples of malformations due to the action of a noxious agent during human development are less numerous Roentgen radiation during the first trimester of pregnancy has been observed to produce a combined cerebral cerebellar defect with mental retardation and ataxia Maternal infection with German measles (rubella) during the first trimester of pregnancy may result in mental defect deafness cataracts and heart disease in the newborn Toxoplasmosis and syphilis may damage the fetal nervous system in the latter half of the period of intrauterine life Isoimmunization by Rh and ABO blood factors may affect the nervous system during the first days of postnatal life leaving in its wake a permanent mental defect choreoathetosis and deafness

Abnormalities of the Head

Alterations in the size and shape of the head when observed in the adult can usually be traced to infancy At least three separate factors are operative (1) the growth thrust of the developing brain and the intracranial pressure (2) the time at which

disease of the brain is its sudden onset and if death does not occur the improvement in the patient s neurologic status Similarly insidious onset and slow progression often punctuated by convulsions are typical of brain tumor

The findings in the general medical examination are of importance the fallacy of studying nervous symptoms and disregarding the general medical findings must be obvious To illustrate low grade fever anemia heart murmur and splenomegaly indicate that in a case of unexplained apoplexy subacute bacterial endocarditis with embolic occlusion of a brain artery is the most likely cause Pleocytosis in the cerebrospinal fluid with elevated protein abnormal gold sol and a positive Wassermann test reaction establish a syphilitic etiology in a case with symptoms of apoplexy a progressive dementia or blindness

The anatomic diagnosis may suggest the etiology of a disease Thus when a unilateral Horner s syndrome cerebellar ataxia paralysis of a vocal cord and analgesia of the face are combined with loss of pain and temperature sensation in the opposite arm trunk and leg an occlusion of the posterior inferior cerebellar artery is suggested because all the involved structures lie within the territory of this artery In a sense the anatomic diagnosis determines and limits the possible disease entities If the signs point to disease of the peripheral nerves it is not necessary to consider the causes of disease of the spinal cord Some signs themselves are almost specific e g Argyll Robertson pupils for neurosyphilis or oculogyric crises for postencephalitic parkinsonism

If one adheres faithfully to the method of making these clinical observations and to the interpretations and methods of reasoning neurologic diagnosis becomes relatively simple In nearly every case it will be possible to reach an anatomic diagnosis The etiology of the disease may prove more elusive Even the most experienced neurologist is unable to ascertain the cause of many neurologic syndromes

THE PURPOSE OF THE CLINICAL METHOD OF NEUROLOGY

Finally a word about the main purposes of the clinical method of neurology Actually diagnosis accomplishes two purposes First it enables the physician to decide on the proper method of treating the ailing patient and second it serves as an essential method in the scientific study of disease by permitting the identification and segregation of clinical phenomena The medical profession is primarily concerned with the prevention and cure of illness and all our knowledge is applied to this well defined end The practical physician applies himself to the diagnosis of diseases for which he has an effective treatment Each of the treatable causes of a given syndrome must be carefully considered and excluded by clinical and laboratory methods In the study of a case of disease of the spinal cord one must take special care to diagnose a tumor subacute combined degeneration spinal syphilis or epidural abscess for these are the treatable spinal cord diseases Failure to recognize amyotrophic lateral sclerosis is a less serious error as far as the patient is concerned The failure to diagnose one case of chronic subdural hematoma is more serious than the incorrect diagnosis of several cases of brain tumor

One cannot agree with those who hold that neurologic diagnosis is merely an intellectual pastime It is true that means are available for treating only a few of the many diseases known to affect the nervous system But there is no doubt that the first step in the scientific study of a disease process is the identification of it in the living patient Until this is achieved it is impossible to apply adequately the master method of controlled experiment The clinical method of neurology thus serves both the physician in the practical diagnosis and treatment of a patient and the clinical scientist who seeks the ultimate cause of disease

253 DEVELOPMENTAL ABNORMALITIES OF THE NERVOUS SYSTEM

Philip R Dodge and Raymond D Adams

The human nervous system is subject to a variety of developmental abnormalities which may be traced to genetic faults or to diseases acquired in utero at birth or during the early years of life

abnormality an accompaniment of an Arnold Chiari *malformation* or of neurofibromatosis or the result of a chronic meningoependymal *inflammation*

3 *Atresia of the foramens of Luschka and Magendie* (*Dandy Walker syndrome*) with obstructive hydrocephalus and enlargement of the posterior fossa Here the basal foramens fail to form or are sealed off and the cerebrospinal fluid cannot enter the subarachnoid space

4 *Chronic meningitis* with communicating or obstructive hydrocephalus This is due to obliteration of the subarachnoid space over the brain stem and/or obstruction of the foramens of Luschka and Magendie The meningitis may be due to syphilis toxoplasmosis or a chronic pyogenic or other in*fection*

5 *A tumor* of the fourth ventricle (medulloblastoma ependymoma or teratoma) of the third ventricle (craniopharyngioma) or of the pineal body (teratoma) may cause obstructive hydrocephalus (see Chap 73)

6 Other conditions such as hypertrophy of the choroid plexuses and achondroplastic dwarfism with hydrocephalus are occasionally observed and finally there is always a large number of patients with hydrocephalus particularly of the communicating type in which a cause can never be established

Subdural Hematoma in Infancy This is a not infrequent cause of a symmetric enlargement of the skull It may occur in several circumstances (1) trauma to the head at birth or later (2) with bleeding diseases or in poorly nourished sickly infants some of whom are said to have had scurvy In acute subdural hematoma the symptoms are the same as those described in Chap 255 on head injury In the chronic subdural hematoma of infancy the initial symptoms are usually irritability vomiting and seizures Later the cranium enlarges symmetrically as a rule even though the subdural hematoma is unilateral X rays of the skull even years later will reveal that a characteristic enlargement of the middle cranial fossa has occurred followed later after resorption or removal of the clot by thickening of the skull and enlargement of the frontal and ethmoidal sinuses (Davidoff and Dyke)

Macroencephaly This is a rare cause of enlargement of the head The brain is malformed and greatly increased in size specimens weighing over 2,500 Gm have been recorded Mental retardation feebleness of movement and enlargement of the head with small ventricles are the criteria for clinical diagnosis The detailed pathologic process is variable and the causes are probably multiple

The *diagnosis* of hydrocephalus is usually established by injecting air directly into the dilated ventricles In the infant this is usually done by inserting a needle through the lateral border of the anterior fontanel The subdural space can also be entered during this maneuver and the aspiration of it will rule out chronic subdural hematoma If *the cortical mantle is thin or the subarachnoid space* dilated cerebrospinal fluid may be obtained and mistaken for subdural fluid In the older child or adult pneumoencephalography burr holes and inspection of the dura must be used Macroencephaly is distinguished by the small lateral and third ventricles The entrance into the ventricles of air that has been introduced into the lumbar subarachnoid space or the passage of a dye such as phenol sulfonphthalein injected into the lateral ventricles to the lumbar subarachnoid space is of help in determining whether or not the hydrocephalus is due to an obstruction in the ventricle system (*obstructive* hydrocephalus) or *is nonobstructive* (also called *communicating* hydrocephalus) The latter is usually due to obliteration of subarachnoid space over the medulla pons and midbrain by a fibrosing meningitis Thrombosis of the superior sagittal sinus may cause headache and elevated intracranial pressure but does not expand the ventricles

The *treatment* of these conditions is relatively unsatisfactory If the hydrocephalus has stabilized *i e the head is no longer enlarging no treatment* should be undertaken If the head is large and the patient is mentally enfeebled or has other serious malformations surgical therapy is ill advised If the hydrocephalus is definitely progressive but the patient s neurologic status is good a number of operative procedures should be tried With obstruction of the aqueduct or fourth ventricle the Torkildsen procedure (short circuiting the fluid *through a tube from the occipital horn of the lateral* ventricle to the cisterna magna) has given the best results Some cases of communicating hydrocephalus have been helped by procedures which shunt the cerebrospinal fluid into the mastoid ureter fallopian tube peritoneal cavity jugular vein or spinal epidural space The treatment of chronic subdural hematoma is repeated percutaneous aspiration by needle and in some cases removal of the *membranes enclosing the subdural hematoma* must be carried out at a later stage Nothing can be done about macroencephaly

Deformity of the Skull The usual cause of a severely misshapen head in the adolescent or adult is cranial dysostosis The cause of this premature fusion or synostosis of one or several cranial sutures is unknown but the most plausible explanation is that the mesenchymal tissues which form the cranial bones *are defective the premature ossi*fication being secondary The occasional association of cranial synostosis with syndactylism (Apert s syndrome) has been cited in support of this hypothesis The developmental defect and synostosis are believed to date from intrauterine life Closure of the sagittal suture results in an elongated doli

the suture lines close (3) the existence of external pressures against the skull In addition a depressed fracture cephalohematoma craniocele or tumor may cause a localized cephalic deformity

It is the constant outward pressure of the developing brain which causes the head to enlarge rapidly in the first months and years of life The proof of this observation is that any disease which destroys a substantial portion of the cerebral hemispheres in infancy will result in microcephaly and conversely excessive intracranial pressure as from hydrocephalus or chronic subdural hematomas enlarges the head to an abnormal degree Focal lesions e g destruction of one hemisphere result in smallness of the skull on that side and a unilateral subdural hematoma enlarges it Regarding premature closure of the sutures (synostosis) it should be noted that this may occur without abnormality of the brain If all sutures close cranial expansion is prevented or if some sutures close and others remain open enlargement will occur only at the latter sites and the skull then becomes deformed A flattening of one side of the head (plagiocephaly) often is found in defective or sick infants who lie in one position for prolonged periods of time The weight of the head against the bed prevents part of the skull from expanding but the cranial capacity is usually undiminished for there is a bulge in another direction usually on the opposite side This deformity will persist if the abnormal positioning continues beyond the period of maximal brain growth Congenital depressions have been observed to result from the prolonged pressure of a fetal hand or foot against the cranial bones in utero

Macrocephaly (Enlargement of the Head) A general enlargement of the head must be distinguished from a misshapen head one that is enlarged in one direction only Three different conditions must be considered in the differential diagnosis—infantile hydrocephalus infantile chronic subdural hematoma and macroencephaly

Hydrocephalus This most frequent cause of enlargement of the head is the only condition in which there is enormous enlargement The majority of severely hydrocephalic infants die within a few months or years and are not seen by internists but a few linger on Sometimes the hydrocephalus becomes arrested and there is a long term survival Hydrocephalus was discussed in Chap 31 Cerebrospinal Fluid and here it is necessary only to point out some of the characteristic changes which the skull undergoes Prominence of the frontal and parietal eminences (hydrocephalic bossing) depression of the orbits relatively low position of the ears dwarfing of the face by the broad expanse of forehead and wide eyed" or staring expression with sclera showing between the upper lid and iris are obvious in the more advanced cases The skin of the scalp is thin and tightly stretched and the subcutaneous veins are prominent The anterior fontanel is nearly always open and full and usually the posterior one which should be closed by the fourth or fifth month remains open During infancy percussion of the head in the parietal region with the finger gives a cracked pot or ripe melon sound (Macewen s sign) With a bright flashlight there may be *excessive transillumination* of the head in the region of the cerebral hemispheres a finding noted in severe degrees of hydrocephalus in hydranencephaly (a condition in which there is a combination of developmental defect in the cerebral tissue and hydrocephalus) and rarely in severe destructive lesions of the brain that occur in utero or in early life (The cerebrospinal fluid does not impede the transmission of light as does brain tissue) Similarly the posterior fossa will transilluminate in the type of hydrocephalus caused by atresia of the foramens of Magendie and Luschka in which the recesses of the fourth ventricle are greatly dilated In older children and adults with large heads due to hydrocephalus neither Macewen s sign nor transillumination may be demonstrated Roentgenograms confirm the enlargement and altered configuration of the head and also show the characteristic digital markings in the frontal and parietal bones

The chronic hydrocephalic syndrome consists of mental dullness slight ataxia mild pyramidal tract signs and impaired vision In the late stages of advancing hydrocephalus the child is usually bed fast seemingly unable to support the enormous head upon the frail body He becomes emaciated his cry is shrill he is blind and has pale optic disks the legs are moved feebly if at all the tendon reflexes are lively and Babinski signs are easily elicited in many cases Ulceration of the scalp may occur Death ultimately results from inanition and infection usually during the first year of life However some patients live on for years and may eventually come under the care of the general physician Not infrequently the illness is terminated by *Escherichia coli Bacillus pyocyaneus* or other unusual types of meningitis

Congenital hydrocephalus may appear years after birth If the sutures have already closed (after the twelfth year) the head cannot enlarge and the hydrocephalus is poorly tolerated Increased intracranial pressure with papilledema vomiting and mental dullness are the usual signs

The usual causes of hydrocephalus are

1 *Arnold Chiari malformation with spina bifida and meningomyelocele*

2 *Atresia or stenosis of the aqueduct of Sylvius* with obstructive hydrocephalus and a small normal appearing posterior fossa This may be an inherited

platybasia fusion of the atlas and occiput or of vertebras (Klippel Feil syndrome) or congenital dislocation of the atlas are the consequence of a malformation of the spine itself and the enclosed spinal cord may or may not be involved Others such as spina bifida occulta spinal meningocele or myelomeningocele or dysraphism involve the whole neural tube including spinal cord investing meninges vertebral bodies and even the overlying skin and subcutaneous tissues

In many of these patients the neurologic defect which appears in infancy does not shorten life in others it becomes manifest only during adult life

Primary Malformations of Vertebras These are most frequent in the cervicooccipital region

The Klippel Feil Deformity This abnormality consists of maldevelopment and fusion of two or more cervical vertebrae resulting in a short neck of limited mobility The hairline is low often at the level of the first thoracic vertebra There may or may not be associated neurologic symptoms or signs The importance of the spinal deformity lies in its frequent association with other abnormalities especially platybasia and syringomyelia

Platybasia (Basilar Impression) In this mal development of the base of the skull there is invagination of the occiput and upper cervical spine into the posterior fossa Often the foramen magnum itself is imperfectly developed or the atlas and occiput are fused The exact teratogenesis of this anomaly is uncertain It may in some instances be asymptomatic but frequently there is crowding distortion or compression of the spinal cord medulla and cranial and spinal nerves The resulting *clinical* picture is variable Symptoms may be present from early life or may begin in late childhood adolescence or even adult years Early symptoms in patients old enough to give a history consist of dizzy" or weak" spells occipital neuralgia transient paresthesias in the occipital region neck or arm double vision facial paresthesias and deafness cerebellar ataxia and spastic weakness of the legs The symptoms may at first be intermittent and at any time in the course of the illness may be aggravated by straining moving the head or placing the head and neck in certain positions Inspection alone provides a clue to diagnosis The whole configuration of the head and neck is unnatural The neck is short the ears and hairline are low neck movements are obviously restricted and the normal cervical lordosis is lost or greatly exaggerated sometimes to the extent that the occiput lies almost on the upper dorsal spine and shoulders

Platybasia and these related anomalies of the spine should be suspected in all cases presenting progressive cerebellar brain stem and cervical cord syndromes Many of these patients have been diagnosed as having multiple sclerosis The clinical suspicion of platybasia can be confirmed by a true lateral roentgenogram of the skull In such a projection the extension of a line drawn from the hard palate and posterior border of the foramen magnum (Chamberlain s line) and another through the spine and body of the first cervical vertebra (Bull s line) instead of being more or less parallel as they normally are intersect when extended This has proved to be the most useful measurement Chamberlain s basal angle obtained by drawing lines along the hard palate and clivus is greater than 135 in *platybasia Also when visible the odontoid process* may project above Chamberlain s line In Towne s view of the skull a malformation or coarctation of the foramen magnum is occasionally found An acquired form of platybasia occurs with rickets and Paget s disease It is usually asymptomatic

The Arnold Chiari Malformation This condition in which medulla and inferior posterior portions of the cerebellar hemispheres project caudally through the foramen magnum often to the level of the second cervical vertebra has already been mentioned as a cause of hydrocephalus It is nearly always associated with a spinal meningocele or *myelomeningocele and often there are deformities* of the cervical spine and cervicooccipital junction The symptoms of hydrocephalus dominate the clinical picture in infants but in milder cases there may develop during adolescence or adult years any one of the several syndromes already described under platybasia When platybasia and the Arnold Chiari malformation coexist it is generally impossible to decide which of the two is responsible for the clinical findings

The cause of the Arnold Chiari malformation itself has been the subject of speculation It has been suggested that the hydrocephalus is primary and that the displacement of the medulla and cerebellum through the foramen magnum is secondary to pressure from above The close relationship to spinal myelomeningocele casts doubt on this explanation The more generally accepted hypothesis is that the associated myelomeningocele causes downward traction on structures in the posterior fossa because *of fixation of the cord to the vertebral* column prior to the period when the growth of the vertebral column outstrips that of the spinal cord The cerebrospinal fluid then flows from the fourth ventricle into the cervical canal cannot reenter the cranial cavity and therefore is not reabsorbed Also the aqueduct of Sylvius is elongated and sometimes critically narrowed (traction stenosis) which may itself account for the hydrocephalus This is not the mechanism in all cases however for examples of the Arnold Chiari *malformation* have been observed without evidence of myelomeningocele Dysraphism of the spinal cord which resembles syringomyelia may accompany both platybasia and

chocephalic head to which the term *scaphocephaly* is applied When the coronal suture fuses prematurely the growth is restricted in the anteroposterior diameter and only lateral and to a lesser extent vertical enlargement may occur This condition is called *brachycephaly* (wide skull) or *acrobrachycephaly* Synostosis of all sutures leaves the cranium small but usually with the greatest growth in the vertical direction the so called *oxycephaly* or *turrencephaly* *Plagiocephaly* refers to an asymmetric deformity of the skull which may be due to synostosis of a single coronal suture or to the application of some external force In *Crouzon's craniofacial dysostosis* acrobrachycephaly is associated with a beak nose This condition is inherited as a mendelian dominant In *Apert's syndrome* webbed or mitten fingers and toes are combined with the Crouzon's defects *Hypertelorism* as described by Greig in 1924 is a rare deformity characterized by wide separation of the eyes and a flat retracted bridge of the nose Mental retardation frequently accompanies the deformity The primary abnormality has usually been ascribed to an abnormally large lesser wing of the sphenoid bone In several instances a dominant mode of inheritance has been found

The most serious complication of synostosis of sutures is a gradual increase in intracranial pressure which occurs during the most active growth period of the brain This tends to be less marked in patients with scaphocephaly than in those with acrobrachycephaly In these patients the orbits are shallow and the eyes bulge Headache divergent strabismus papilledema optic atrophy and later blindness nystagmus mental retardation and behavioral abnormalities are the most striking clinical manifestations Usually the patients require medical attention within the first 2 or 3 years of life though it may be needed later In roentgenograms of the skull one observes the primary suture involvement prominence of convolutional markings and a depression and smallness of the sella turcica

In the absence of increased intracranial pressure the diagnosis of premature closure of the sutures should always raise the suspicion of defective growth of the brain (see below Microcephaly)

The treatment of primary craniosynostosis is surgical and if it is to be effective in preventing permanent injury to the brain it should probably be carried out early in life particularly if one has any intention of lessening the skull deformity The operative procedure is one of making artificial suture lines by removing pieces of bone and inserting a plastic material in their place to prevent regrowth Occasionally this results in a striking improvement in mental function and behavior even in an older child in whom the diagnosis had not been made early in life In other cases progression of the illness is halted Failure to improve even when surgery has been performed early suggests in certain instances that the brain defect is independent of the cranial abnormality

Microcephaly This term is used to designate any condition in which there is an abnormally small head An occipitofrontal circumference of less than 19 in beyond the age of ten years is given as the dividing line between normal and abnormal Microcephaly is accompanied by a reduction in the mass of the brain and two types of pathologic change have been reported There is one form in which the growth disturbance appears to be the sole factor the brain except for its smallness has a normal appearance This is called *microcephaly vera* The other is a focal arrest of growth due either to embryonal failure in development of a part of the cerebral hemisphere (*schizencephaly*) or to an acquired disease which has resulted in destruction of one or both of the cerebral hemispheres (*encephaloclastic microcephaly*)

Microcephaly Vera This condition may occur in several members of one generation of a family and can often be linked to a recessive gene The head tends to be extraordinarily small usually measuring 15 in or less in circumference It is usually of symmetric shape and owing to the lack of frontal prominence resembles the skull of a monkey The ears are large and often malformed The clinical picture varies All patients show simple mental retardation of moderate or severe degree Seizures and quadriparesis have been described in some patients but in the authors experience are much less frequent than in the other forms of microcephaly Those cases with focal arrest of growth or destruction of cerebral tissue schizencephaly and encephaloclastic microcephaly exhibit a wide variety of clinical findings The mental state in the most severe cases is usually that of an idiot and all cerebral functions fail to develop In fact the cerebral hemispheres may be represented only by membranes filled with clear or yellowish fluid *hydranencephaly* In others in which the cerebral defect is restricted to one cerebral hemisphere or part of a hemisphere there may be hemiplegia with a small arm and leg gross hemianesthesia homonymous hemianopia and seizures with lesser degrees of mental backwardness The skull on the side of the damaged hemisphere is smaller and in roentgenograms the frontoparietal bones are thick the middle fossa is shallow and the paranasal sinuses are enlarged

Abnormalities of the Spine of Neurologic Significance

There is a remarkable variety of neurologic syndromes which include an abnormality of the vertebral column Some of these like hemivertebra

which connect them to the skin provide free access for bacteria and are often a source of abscess and recurrent meningitis Evidence of such tracts should be sought in every instance of meningitis in children and adolescents especially when infection has recurred

There are in addition other *congenital cysts* and *tumors* which may produce progressive symptoms and signs by compressing the spinal cord or by implicating nerve roots

DIASTEMATOMYELIA This is another unusual abnormality of the spinal cord Here a bony spicule or ridge protrudes into the spinal canal from the body of one of the thoracic or upper lumbar vertebrae If the bony abnormality is in the thoracic region there will be duplication of or splitting of the spinal cord (diplomyelia) As the vertebral column grows traction is exerted on the less rapidly growing cord The stretched spinal cord is injured ("traction myelopathy") with classical manifestations of urinary and fecal incontinence and sensorimotor dysfunction in the legs Some degree of spina bifida is reported to have occurred in more than half the cases The diagnosis can be made by roentgenograms and myelogram and the bony spicule removed by surgery

These spinal abnormalities are of particular interest to internists when they begin to produce symptoms for the first time in an adolescent or adult Several clinical syndromes have been delineated (1) Progressive spastic weakness of the legs during late childhood or adolescence in a patient known to have had a meningocele or myelomeningocele Presumably the spinal cord which is securely attached to the lumbar vertebrae is stretched during the period of rapid lengthening of the vertebral column (2) An acute cauda equina syndrome following some unusual activity or incident e g rowing or a fall in a sitting position in patients who have had an asymptomatic or symptomatic spina bifida or meningocele The implicated sensory and motor roots are believed to be injured by sudden or repeated stretching Weakness of bladder control impotence (in the male) numbness of feet and legs or foot drop comprise the clinical syndrome (3) Syringomyelia—cf p 1675 (4) Progressive cauda equina syndrome due to a lipoma or dermoid in the lumbosacral region

Malformations of the Extremities

A variety of primary skeletal defects such as absence of or increase in number of digits or extremities fusion or webbing of digits (syndactylism) deformity of digits or limbs or abnormalities of size have neurologic import for they tend to be associated with malformations of the central nervous system For example *syndactylism* is frequently combined with oxycephaly (*Apert s syndrome*) In *mongolism* the fifth digit is unusually short and curved the hands are broad and simian like and there is usually only a single transverse crease in the palm In arachnodactyly the digits are long and tapering a condition frequently linked to disease of the aorta and congenital heart disease and to dislocation of the lens (cf Marfan s syndrome p 1690)

Shortening of all the extremities with normal growth of the trunk is characteristic of achondroplasia In Morquio s syndrome both the trunk and the limbs are short and deformed Thus dwarfism may be importantly linked in this condition with a neurologic abnormality just as it is in cretinism mongolism and gargoylism The sufferers from these several neurologic diseases in which growth is stunted may be referred to collectively as "demented midgets" and since many of them reach adult years they must be treated by general practitioners internists and surgeons for other diseases which develop during this age period

In some cases the deformity of the extremities is the direct consequence of a congenital neuromuscular defect In fact this happens so often that whenever deformities of the limbs are known to have begun early in life one should at once evaluate the status of the nervous system In most cases of *clubfoot* (talipes equinovarus) no abnormality of the nervous system can be ascertained In a few however the deformity results from paralysis of the anterior tibial and peroneal muscles due to a primary defect in the anterior horn cells of the lumbosacral segments of the spinal cord The contracture of calf muscles is secondary Widespread weakness and contractures of many limb muscles may cause extensive deformities (*arthrogryposis multiplex* or *amyoplasia congenita*) This syndrome may also be the result of any one of several other primary neural or muscular diseases such as congenital absence of muscles muscular dystrophy and rarely from infantile motor neurone disease (*Werdnig Hoffmann infantile muscular atrophy*) Reconstructive surgery and the techniques of physical medicine may permit a certain measure of rehabilitation in those cases with nonprogressive diseases However severe mental defects which are frequent in these conditions tend to discourage elaborate programs of therapy

Birthmarks and Associated Neurologic Conditions

A number of neurologic abnormalities are combined with congenital defects of skin or retina explained usually by their common ectodermal origin The terms *congenital ectodermal dysplasias congenital neurocutaneous syndromes* or *phacomatoses* (*phakos* birthmark) are used frequently to desig

Arnold Chiari malformation and manifests itself by segmental weakness atrophy areflexia and sensory loss in the arms and hands Syringomyelia may also occur This is discussed in Chap 259

Methods of treatment of platybasia and the Arnold Chiari malformation have not been entirely satisfactory If clinical progression is slight or uncertain it is probably advisable to do nothing If progression is certain and disability is increasing upper cervical laminectomy and enlargement of the foramen magnum are indicated Sometimes these procedures halt the course of the illness or result in improvement The surgical procedure must be done cautiously however for extensive manipulation of these structures may aggravate the symptoms or even cause death

Malformations Associated with a Defect in Closure of the Neural Arch There are many deformities along the posterior surface of the body that are accompanied by an abnormality in the formation of the posterior aspect of the neural arch and closure of the primitive neural tube The entire neural canal including the cranium may fail to close (*craniorhachischisis totalis*) or there may be only a minute defect in one or more of the vertebral arches demonstrable by roentgenograms (*spina bifida occulta*) The latter is said to occur in one quarter of the population It has been estimated that in approximately one of every 900 births there is a serious closure defect in the spine or more rarely in the cranium

The neural tube is closed and has been separated completely from the anlage of the skeleton by approximately the third week of intrauterine life and by three months the neural arches are completely fused along their dorsal aspect The defects under discussion must then have originated during the early weeks of embryonic life in all probability by the middle of the first month The skeletal malformations may arise at any time prior to the end of the third month The not infrequent occurrence of some of these defects in several siblings attests to their genetic origin and the data suggest a recessive mode of inheritance

Defects of this type may be found at any point along the neuraxis They are most frequent in the lumbosacral and cranial regions less frequent in the cervical region and rare in the thoracic region The character of the abnormality varies There may be an outpouching of neural elements (nerve root and cord) through a defect in mesenchymal tissue and skin (*myelomeningocele*) less often actually in less than one fifth of all cases only a thin walled cyst composed of meninges and containing no neural tissue can be found The cranial defect similarly may consist of an encephalocele with evagination of cerebral tissue and meninges through a midline defect in the membranous bones of the skull These are most often occipital in location though a few may be frontal presenting either anteriorly or inferiorly into the nasal cavity Probably the most astonishing cranial defect of all and one nearly as frequent as the myelomeningocele is *anencephaly* In this condition there is a gross defect or absence of the membranous bones of the skull the cerebral hemispheres and corpus striatum are also absent and the remainder of the brain grossly malformed Patients with severe defects of this type usually do not survive

MENINGOCELE AND MYELOMENINGOCELE Meningocele may exist alone and unaccompanied by any symptoms or signs Myelomeningocele in contrast is associated with some dysfunction of those nervous structures that lie within the wall of the sac The signs may be minimal limited to sensorimotor dysfunction of a few segments or pronounced with total paraplegia and incontinence of urine and feces Severe paralysis and wasting of muscles in the legs may result in contractures and various skeletal deformities such as *clubfoot* or *arthrogryposis multiplex congenita* (see Malformations of the Extremities further on in this chapter) Such cases show a susceptibility to decubitus ulcers and not infrequently there is infection of the sac and neighboring tissues When the defect involves only the meninges or a few roots the neurologic defect may not be apparent at birth After a year or two attention is directed toward this possibility by the discovery of contracture feebleness of movement smallness of muscles of the legs or by some urologic disorder

The decision to operate upon these infants with total paralysis of the legs and of the rectal and bladder sphincters may be questioned One must be alert to the development of hydrocephalus either before or after operation on the spinal lesion This almost always means an associated Arnold Chiari malformation as already stated Some of these cases can be helped by craniocervical decompression

OTHER ABNORMALITIES RELATED TO A DEFECT IN CLOSURE OF NEURAL CANAL These are often indicated by a small dimple in the skin or by a tuft of hairs along the posterior surface of the body in the midline These signs occur most often in the lumbosacral and occipital regions and are thought to represent failure of closure of the anterior or posterior neuropores (The pilonidal sinus in the opinion of the authors should not be included in this group) Small sinus tracts may exist at these points and are of clinical importance because they frequently connect with the central nervous system or its coverings and are not uncommonly associated with dermoid cysts at the central end of the tract These cysts most often occur in the cerebellum or in the lumbosacral regions and the sinus tracts

which connect them to the skin provide free access for bacteria and are often a source of abscess and recurrent meningitis Evidence of such tracts should be sought in every instance of meningitis in children and adolescents especially when infection has recurred

There are in addition other *congenital cysts* and *tumors* which may produce progressive symptoms and signs by compressing the spinal cord or by implicating nerve roots

DIASTEMATOMYELIA This is another unusual abnormality of the spinal cord Here a bony spicule or ridge protrudes into the spinal canal from the body of one of the thoracic or upper lumbar vertebrae If the bony abnormality is in the thoracic region there will be duplication of or splitting of the spinal cord (diplomyelia) As the vertebral column grows traction is exerted on the less rapidly growing cord The stretched spinal cord is injured ("traction myelopathy") with classical manifestations of urinary and fecal incontinence and sensorimotor dysfunction in the legs Some degree of spina bifida is reported to have occurred in more than half the cases The diagnosis can be made by roentgenograms and myelogram and the bony spicule removed by surgery

These spinal abnormalities are of particular interest to internists when they begin to produce symptoms for the first time in an adolescent or adult Several clinical syndromes have been delineated (1) Progressive spastic weakness of the legs during late childhood or adolescence in a patient known to have had a meningocele or myelomeningocele Presumably the spinal cord which is securely attached to the lumbar vertebrae is stretched during the period of rapid lengthening of the vertebral column (2) An acute cauda equina syndrome following some unusual activity or incident e g rowing or a fall in a sitting position in patients who have had an asymptomatic or symptomatic spina bifida or meningocele The implicated sensory and motor roots are believed to be injured by sudden or repeated stretching Weakness of bladder control impotence (in the male) numbness of feet and legs or foot drop comprise the clinical syndrome (3) Syringomyelia—cf p 1675 (4) Progressive cauda equina syndrome due to a lipoma or dermoid in the lumbosacral region

Malformations of the Extremities

A variety of primary skeletal defects such as absence of or increase in number of digits or extremities fusion or webbing of digits (syndactylism) deformity of digits or limbs or abnormalities of size have neurologic import for they tend to be associated with malformations of the central nervous system For example *syndactylism* is frequently combined with oxycephaly (*Apert s syndrome*) In *mongolism* the fifth digit is unusually short and curved the hands are broad and simian like and there is usually only a single transverse crease in the palm In arachnodactyly the digits are long and tapering a condition frequently linked to disease of the aorta and congenital heart disease and to dislocation of the lens (cf Marfan s syndrome p 1690)

Shortening of all the extremities with normal growth of the trunk is characteristic of achondroplasia In Morquio s syndrome both the trunk and the limbs are short and deformed Thus dwarfism may be importantly linked in this condition with a neurologic abnormality just as it is in cretinism mongolism and gargoylism The sufferers from these several neurologic diseases in which growth is stunted may be referred to collectively as "amented midgets" and since many of them reach adult years they must be treated by general practitioners internists and surgeons for other diseases which develop during this age period

In some cases the deformity of the extremities is the direct consequence of a congenital neuromuscular defect In fact this happens so often that whenever deformities of the limbs are known to have begun early in life one should at once evaluate the status of the nervous system In most cases of *clubfoot* (talipes equinovarus) no abnormality of the nervous system can be ascertained In a few however the deformity results from paralysis of the anterior tibial and peroneal muscles due to a primary defect in the anterior horn cells of the lumbosacral segments of the spinal cord The contracture of calf muscles is secondary Widespread weakness and contractures of many limb muscles may cause extensive deformities (*arthrogryposis multiplex* or *amyoplasia congenita*) This syndrome may also be the result of any one of several other primary neural or muscular diseases such as congenital absence of muscles muscular dystrophy and rarely from infantile motor neurone disease (*Werdnig Hoffmann infantile muscular atrophy*) Reconstructive surgery and the techniques of physical medicine may permit a certain measure of rehabilitation in those cases with nonprogressive diseases However severe mental defects which are frequent in these conditions tend to discourage elaborate programs of therapy

Birthmarks and Associated Neurologic Conditions

A number of neurologic abnormalities are combined with congenital defects of skin or retina explained usually by their common ectodermal origin The terms *congenital ectodermal dysplasias congenital neurocutaneous syndromes* or *phacomatoses* (*phakos* birthmark) are used frequently to desig

nite this general class of disorders The major syndromes include *neurofibromatosis tuberous sclerosis encephalotrigeminal syndrome* and rarely the *cerebelloretinal hemangioblastomatosis* Another variant of the latter is the *myelocutaneous syndrome* in which a vascular malformation of spinal cord and meninges is associated with a vascular nevus within the area of skin innervated by the involved spinal segments

Neurofibromatosis (von Recklinghausen s Disease) This is an inherited disease (mendelian dominant) in which spots of increased skin pigmentation are combined with multiple neurofibromas The pigmented spots are irregular in shape with relatively even borders vary in size from a few millimeters to several centimeters and are of brownish-coffee color (cafe au lait) They are most prominent over the trunk and especially about the pelvis Similar lesions occur in people without neurofibromatosis but in such instances are generally smaller than 2 cm in diameter and fewer than five in number The tumors arise from the neurilemmal sheath (Schwann cells) and fibroblasts of the peripheral nerve They are usually multiple and vary in size from minute lesions to large tumors several centimeters in diameter The majority are smoothly rounded or lobulated soft or firm and can sometimes be seen or felt along the course of a peripheral nerve Often they sink into the subcutaneous fat on gentle pressure Like the pigmented lesions the tumors are more frequent over the trunk than on the extremities The pigmented areas of skin may be visible in infancy though usually they become increasingly apparent with age the tumors of nerve sheaths are often not demonstrable early in life Most of the tumors in neurofibromatosis are asymptomatic but occasionally if they attain a large size or occupy an unusual position they may produce symptoms by pressing upon contiguous structures Tumors of the spinal nerves may compress the spinal cord and at the same time extend through the intervertebral foramens to form a large mass in the posterior mediastinum (dumbbell tumors) Acoustic neurinomas usually bilateral in patients with neurofibromatosis may produce deafness and symptoms and signs of a cerebellopontine angle tumor Other histopathologic types of tumor (meningioma glioma) are encountered more frequently in neurofibromatosis than in the general population Most of these tumors are rare in infancy and childhood though glioma of the optic nerve is an exception to this clinical rule The latter condition should always be considered in the differential diagnosis of unilateral (rarely bilateral) blindness proptosis and extraocular muscle paralysis in childhood especially if there are signs of von Recklinghausen s disease Enlargement of the optic foramens demonstrable by roentgenogram is a valuable aid in diagnosis Pheochromocytoma is an infrequent accompaniment of the disease In about 5 to 10 per cent of cases of neurofibromatosis one of the tumors will become sarcomatous

Fibrous dysplasia congenital vertebral anomalies local gigantism of an extremity subperiosteal bone cysts and pseudoarthrosis of the tibia may be associated with neurofibromatosis Any of these can lead to scoliosis a common skeletal deformity in children with this disease so that neurofibromatosis must be added to the list of neurogenic kyphoscolioses (the others are syringomyelia Friedreich s ataxia and poliomyelitis) Stenosis of the aqueduct with obstructive hydrocephalus is at times observed in neurofibromatosis Also mental retardation is rather common in families with von Recklinghausen s disease though its pathogenesis is not at all understood Spina bifida hypospadias glaucoma and elephantiasis are occasionally seen

There is no treatment for the disease other than excision of tumors which cause pressure on a nerve

Tuberous Sclerosis (Bourneville s Disease) This curious disease of dominant inheritance is manifested by the clinical triad of convulsive seizures progressive mental deficiency and adenoma sebaceum The latter are fine wartlike lesions predominantly in a butterfly distribution over the cheeks and forehead The individual adenomas vary in size from 0 1 to 1 0 cm and are elevated and pinkish or pinkish yellow in color In addition the skin over the lower back may be thick rough and of yellowish color (shark skin patch shagreen) The mental deficiency may be relatively stationary or progressive The seizures are usually generalized but may be focal Retinal tumors optic atrophy cataracts and hyperonchomas syndactylism spina bifida and other visible malformations may be conjoined

The lesions of the skin are pathologically fibromas and not true adenomas Some are rather vascular and suggest telangiectasia The brain lesions consist of areas of malformed cortex with extensive astrogliosis and a curious mixture of glioblasts and monster nerve cells Calcification may or may not be present Masses of subependymal glial tissue account for nodules which project into and form the candle götterings on the walls of the ventricles that are often seen in pneumograms In Bourneville s original case death was due to rhabdomyoma of the heart This lesion has been combined in some cases with vascular malformations of kidney liver adrenal glands and pancreas

The diagnosis is aided by roentgenograms of the skull Calcified nodules occur particularly in the temporal lobe The center of the nodule tends to be more densely radiopaque than the periphery

The EEG is usually abnormal but without specific pattern The cerebrospinal fluid may be normal rarely the total protein is elevated

The only treatment is symptomatic The prognosis for life beyond the third decade is poor Death may be due to seizures associated tumors or intercurrent diseases

Cerebelloretinal Hemangioblastomatosis (Lindau s and von Hippel s Disease) This condition is discussed here though the skin is seldom involved As the name implies the syndrome consists of a vascular malformation of retina and cerebellum The retinal lesion usually has the characteristics of a malformation whereas the cerebellar lesion consists of a slowly growing cystic tumor The clinical symptoms and signs consist of progressive cerebellar ataxia headache and papilledema Polycythemia of undetermined etiology has been observed in many cases and has in a few instances disappeared after excision of the tumor Rarely do these tumors appear before adolescence Some cases are familial (mendelian dominant)

This condition is often associated with malformation of other organs especially with visceral tumors Angiomas of the liver cysts of the pancreas and kidneys and tumors of the epididymus and kidney which have been the cause of death in some cases are the major parts of the syndrome Pheochromocytomas have been described in this and in other of the phakomatoses Syringomyelia has been observed in a few cases and if a careful search is made a hemangioblastoma can often be found in relation to the syrinx at some level

The cerebellar hemangioblastoma demands surgical treatment and if the nodule of tumor is found in the wall of the cyst and is excised the results can be excellent

Encephalotrigeminal Syndrome (Sturge Weber Dimitri Disease) This curious disease consists of capillary or cavernous hemangiomas within the cutaneous distribution of the trigeminal nerve and of a predominantly venous hemangioma of the leptomeninges If the skin lesion is within the area of supply of the ophthalmic division of the trigeminal nerve the occipital lobes are more commonly involved whereas a facial nevus is more often associated with involvement of the parietal and frontal lobes The intracranial or cutaneous lesion may occur separately

Pathologically in addition to the large number of abnormal blood vessels in the meninges the cortex is destroyed and in some cases a band of calcium develops within the lesion This band following the convolutional pattern as it does is responsible for the characteristic roentgenographic picture

The first neurologic symptom is usually a focal seizure on the side opposite the skin lesion Transient postictal (Todd s) paralysis may follow the seizure Sensorimotor paralysis or permanent visual field defect the most frequent findings may be either of insidious onset and slow progression or apoplectic sometimes with bloody spinal fluid indicating rupture of a subarachnoid vessel In fact repeated hemorrhages into the meninges have been reported Possibly occlusion of cortical vessels will in certain instances be responsible for neurologic deficits Blindness in the eye on the side of the nevus is frequent and is nearly always due to glaucoma Most patients with this malformation survive for many years often with residual mental and other neurologic defects

The lesions are usually too extensive to be treated surgically though hemispherectomy has been advised by some surgeons Anticonvulsant medication is indicated but the seizures may be difficult to control

Abnormalities of Motor Function (Cerebral Palsy)

In this category of neurologic defect a major disturbance of motor function usually nonprogressive has been present since infancy or childhood The popular term for these conditions is *cerebral palsy* The name is not altogether appropriate nor is such a crude classification of nervous disorders particularly useful from the viewpoint of the physician because it results in a collocation of diseases of widely differing etiologic and anatomic types The hereditary and acquired the intrauterine natal and postnatal diseases lose their identity Nevertheless the term has been adopted as a slogan for fund raising societies and for a major rehabilitation movement throughout the United States and it will not soon disappear from medical terminology

Clinical Approach to Motor Disturbances Which Have Developed in Infancy or Childhood

Motor abnormalities which have their onset early in life are so numerous and diverse that it is necessary to acquire some knowledge of the motor system in order to interpret them Also a classification is useful in guiding one s thinking It is helpful to attempt to categorize a given case according to the extent and nature of the abnormality

CLASSIFICATION OF DEVELOPMENTAL MOTOR ABNORMALITIES

I Spastic or rigid paralyses
- *A* Cerebral spastic diplegia and paraplegia
- *B* Infantile hemiplegia
- *C* Double hemiplegia
- *D* Quadriplegic states

II Extrapyramidal syndromes
- *A* Choreoathetosis and dystonia
- *B* Cerebellar ataxia

nate this general class of disorders The major syndromes include *neurofibromatosis tuberous sclerosis encephalotrigeminal syndrome* and rarely the *cerebelloretinal hemangioblastomatosis* Another variant of the latter is the *myelocutaneous syndrome* in which a vascular malformation of spinal cord and meninges is associated with a vascular nevus within the area of skin innervated by the involved spinal segments

The lesions of the skin are pathologically fibromas and not true adenomas Some are rather vascular and suggest telangiectasia The brain lesions consist of areas of malformed cortex with extensive astrogliosis and a curious mixture of glioblasts and monster nerve cells Calcification may or may not be present Masses of subependymal glial tissue account for nodules which project into and form the candle gutterings on the walls of the ventricles that are often seen in pneumograms In Bourneville s original case death was due to rhabdomyoma of the heart This lesion has been combined in some cases with vascular malformations of kidney liver adrenal glands and pancreas

The diagnosis is aided by roentgenograms of the skull Calcified nodules occur particularly in the temporal lobe The center of the nodule tends to be more densely radiopaque than the periphery

birth or during the first 6 to 12 months of life Acquired forms following an infection or thrombosis of cerebral arteries or veins usually develop later The parents may be the first to notice that movements of prehension and exploration are carried out with only one arm The affection of the leg is usually recognized later i e during the first attempts to walk

The cardinal feature of a cerebral hemiplegia and this also applies to diplegia is that it is partial the limbs will always move under certain circumstances The most satisfactory tests are the facility with which the two arms engage in manipulative prehensile and exploratory movements The latter may be examined in the first weeks of life by placing the infant on his feet and making him step forward by advancing and tipping the trunk from side to side Hand preference during the first 2 to 3 years of life should always raise a suspicion of a motor defect on the opposite side

If the brain lesion responsible for the hemiplegia is of recent onset (at birth or shortly before) and the cerebral lesion extensive one may observe sluggishness of all motor responses poor sucking reflexes difficulty in breathing and irregular pulse The tendon reflexes tend to be more active on the affected side and the plantar reflexes more definitely extensor in type than on the normal side There may be a homonymous visual field defect as shown by a neglect of dangling objects on one side or a unilateral somatic sensory loss indicated by a lesser response to tickle a vibrating tuning fork and painful stimuli The muscular tone is usually normal

An assessment of the neurologic status at the end of the first and second years reveals more clearly the extent of the motor defect The hand and fingers are clumsy and slow Often the fingers are hyperextensible and in one third of cases they exhibit athetotic movements and postures in which the wrist is strongly flexed metacarpal phalangeal joints are extended and phalangeal joints are variably flexed or extended in various sequences The adult hemiplegic attitude i e the arm adducted at the shoulder flexed and internally rotated at the elbow pronated and flexed at wrist and fingers with the thumb adducted and covered by the fingers and the leg adducted and internally rotated at the hip with the foot inverted and plantar flexed is evident at this time Contractures may be found in the hip flexors hamstrings and plantar flexors of the foot Sitting standing and walking are delayed but not so frequently as in cases of cerebral diplegia Improvement may be noticed as the child grows and matures especially if there has been a severe sensory defect Impaired sensation appears to retard motor development early in life but later is compensated for even though such patients retain their sensory defects At a more advanced age when sensory testing can be done specific difficulties of proprioception two-point localization recognition of form by feeling an object and failure to appreciate a stimulus on the involved side when one is simultaneously applied to the other side can be demonstrated in about a fourth of these cases Smallness or hypoplasia of the hemiplegic extremities (hemiatrophy) is another common finding especially during adolescent and adult years The use of a limb appears to be a necessary stimulus to its growth Hemiatrophy in the adult always means that the neurologic deficit began before growth had proceeded very far usually in childhood or before

Mental defect may be associated with infantile hemiplegia but is much more common with cerebral diplegia and with bilateral hemiplegia Convulsions occur in 35 to 50 per cent of children with congenital hemiplegia They may commence at any time of life but more often in infancy or early childhood if the disease was congenital If the hemiplegia was acquired during infancy seizures often accompany the onset They may be generalized but are frequently unilateral and limited to the hemiplegic side Often after a series of seizures the affected side will be weak for several hours or longer (Todd's paralysis)

Double Hemiplegia This term is applied to bilateral weakness of face arms and legs The arms are severely affected in contrast to their minimal affection in cerebral diplegia Difficulty with breathing sucking and swallowing is usually noted in the neonatal period if the illness began at or before birth Weakness and spasticity are apparent at an early age Opisthotonos with flexed arms and extended legs is the usual attitude and is exaggerated during periods of crying The cry itself tends to be high pitched and shrill Mental development is almost invariably retarded and such children usually never learn to sit walk or develop any effective use of the limbs The bulbar musculature is also affected Choreoathetosis blindness and seizures occur in many of the patients The head tends to be small in children with double hemiplegia reflecting the small size of the brain In other respects bilateral hemiplegia does not differ from unilateral hemiplegia

Quadriplegic States Differing from bilateral hemiplegias in that the bulbar musculature is not involved this condition is relatively rare but may result from a bilateral cerebral lesion However a spastic quadriplegia should always alert one to the possibility of a high cervical cord lesion Although this may occasionally result from cysts tumors and other malformations it is usually produced in the infant by a fracture dislocation of the cervical spine incurred during a difficult breech delivery Crothers and Putnam state that an audible snap may be heard at the time of fracture If the condition goes

III Flaccid paralyses
- A Generalized
  - 1 Cerebral type—cerebral atonic diplegia (of Foerster)
  - 2 Spinal type
    - a Infantile muscular atrophy of Werdnig Hoffmann
    - b Traumatic necrosis of spinal cord
  - 3 Other types
    - a Infantile muscular dystrophy
    - b Lipoid and glycogen storage diseases
    - c Infantile polymyositis
    - d The slack child and amyotonia congenita of Oppenheim
- B Localized (nerve)
  - 1 Brachial plexus palsies of Erb and Klumpke
  - 2 Facial palsy
  - 3 Other peripheral nerve palsies

These motor abnormalities of infancy and childhood are relatively frequent and many of the affected children reach adult years

Special Types

Infantile Spastic and Rigid Paralyses The pattern of paralysis or rigidity is important for it provides information as to the etiology and possible pathogenetic mechanism

Cerebral Spastic Diplegia (Little's Disease) In 1862 Little called attention to the concurrence of "Abnormal Parturition Difficult Labours Premature Birth and Asphyxia Neonatorum and of a spastic weakness that affected legs more than arms He emphasized the prenatal or natal origin the diplegic (legs > arms) distribution of the paralysis and the nonprogressive course Little was of the opinion that birth trauma or asphyxia caused the cerebral damage but further studies by Freud Osler Ford and others have cast doubt on this explanation by showing the existence of congenital and hereditary forms The present view is that it represents a syndrome of multiple etiology and of diverse pathology

S A K Wilson distinguishes three types the paraplegic diplegic and the generalized and pseudobulbar These differ from one another only in respect to the severity of affection of the arms and bulbar musculature Pure paraplegias and pure pseudobulbar cases are relatively rare Usually all four extremities are involved the legs much more than the arms As a rule the abnormality is recognized at birth or soon thereafter by some abnormality of breathing sucking and swallowing color of mucous membranes or responsiveness These latter signs may indicate either a congenital defect of the nervous system or birth injury The stiff awkward movements of the legs maintained in an extended adducted posture attract attention at this time or in the ensuing weeks Seizures occur in some cases and it is not uncommon to observe a delay in all the normal developmental sequences especially those which depend on the motor system Once walking is attempted the characteristic stance and gait become manifest The legs are advanced stiffly in short steps each describing part of the arc of a circle adduction is often so strong as to lead to actual crossing (scissors gait) with lower legs slightly splayed out and the feet flexed and turned in the heels no longer touching the ground The legs tend to be thin but the muscles are not markedly atrophic as in infantile muscular atrophy and dystrophy Passive manipulation of the limbs reveals marked spasticity in the extensors and adductors and also slight contracture of calf muscles The hands and arms may be little if at all affected but in many cases there is awkwardness and stiffness of the fingers and in a few pronounced weakness and spasticity Speech may be well articulated or noticeably slurred and often the face is set in a spastic smile The deep tendon reflexes are exaggerated those in the legs more than in the arms and the plantar reflexes are extensor Usually there is no disturbance of sphincteric function though delay in acquiring voluntary function is usual Athetotic postures and movements of the face tongue and hands are present in some cases and may actually conceal the pyramidal weakness Ataxic and hypotonic forms also exist The mentality ranges from normalcy to idiocy

Surprisingly little information has been obtained concerning the cause mechanism and morbid anatomy of this syndrome The claim that birth injury is responsible has been challenged and the existence of an antenatal lesion can no longer be doubted A familial variety of spastic diplegia is now well documented but such a genetic determination applies to only a minority of cases and the progressive nature of the illness readily distinguishes this disease from the conditions under discussion (see p 1675) The brain has appeared grossly normal in some instances and the only microscopic abnormality has been an absence of Betz cells and a poorly myelinated corticospinal tract It is as though the corticospinal system had failed to develop In others a diffuse loss of nerve cells and gliosis of cerebral cortex (mantle sclerosis) has been found Shrunken atrophic convolutions with or without cavitation of white matter (ulegyria) a restricted form of which may involve only a few convolutions has probably been the most frequent pathologic finding The pathologic findings give little information as to the original process except that it must have occurred after cerebral development was nearly complete

Infantile Hemiplegia In this not uncommon condition of infancy and childhood a functional difference between the two sides may be noticed at

deformed walking on the heels or side of the foot is more common than the "toe walking" of the cerebral diplegic Movements may also be ataxic and tremors are not uncommon A retardation of motor development is the rule in these cases Upright posture and walking may in fact never be acquired or may be delayed until the age of three to five years in severe cases but thereafter more or less effective locomotion is possible The tendon reflexes are not consistently abnormal plantar reflexes are characteristically flexor though they may be difficult to interpret because of the continuous play of flexor and extensor movements of the toes The various sensory pathways usually function normally

It is because of the motor and speech impairment that patients are many times erroneously classified as mentally defective No doubt in some patients this evaluation is correct but others retain adequate intellectual function and can be educated With growth and development new postures and new motor capacities are acquired The less severely affected patients can make successful occupational adjustments However the severely handicapped patients even with the help of rehabilitation clinics and corrective orthopedic operations rarely achieve a degree of motor control that will permit them to lead an independent existence One sees these unfortunate individuals in public places bobbing and weaving as they walk along

The most frequently observed pathologic change in the brain has been a curious whitish marblelike appearance of the putamen thalamus and cerebral cortex These whitish strands represent foci of nerve cell destruction and gliosis with a peculiar condensation or formation of myelinated fibers (hypermyelination) Oscar and Cecile Vogt who first described this condition called it *etat marbre* or *status marmoratus* They attributed it to neonatal asphyxia, but the hypoxic factor is far from established

The *neurologic sequelae* of *kernicterus* are of importance here and are encountered not infrequently in adults It is true that the majority of infants who suffer this disease die within the first week or two of life and those who survive are mentally retarded deaf and totally unable to sit stand or walk so that the tendency is always to put them in homes for the feebleminded It is only the exceptional patient obviously less damaged who is mentally normal or at most only slightly backward These are the ones who exhibit a variety of motor disorders as they grow older the most frequent being mild ataxia or choreoathetosis which involves the face and arms A few have also shown rigid limbs and a picture not too different from that of cerebral spastic diplegia with involuntary movements Kernicterus should always be suspected if an extrapyramidal syndrome is accompanied by bilateral deafness and ocular palsies The neuropathology in these milder surviving cases consists of nerve cell loss and gliosis in the subthalamic nucleus of Luys the globus pallidus thalamus Ammon's horn and oculomotor and cochlear nuclei No one explanation of the neurologic lesion has been accepted Elsewhere we have postulated severe liver damage and hyperbilirubinemia as a cause of the brain disease but this hypothesis is unproved Others attribute the brain damage to hypoxia

Congenital Ataxia The combination of cerebral diplegia with cerebellar ataxia has already been mentioned These are cases in whom difficulty in standing and walking cannot be attributed to spasticity or paralysis Incoordination similar to that seen in cerebellar disease and hypotonia are the principal findings The motor defect may be so great that the child is never able to sit or stand the muscles are of normal size and voluntary movements though weak are possible in all the limbs In less severe cases sitting standing and walking are merely delayed and with advancing years cerebellar ataxia and tremor become manifest Relative improvement may occur as the child grows older The tendon reflexes are present and the plantar reflexes are either flexor or extensor Many of these patients suffer a degree of amentia and retardation of speech development that results in their placement in homes for the feebleminded In relatively few of the recorded cases has the pathology of this condition been studied Aplasia or hypoplasia of the cerebellum has been reported only a few times X ray radiation of the abdomen of a parturient woman during the first trimester of pregnancy has resulted in cerebellar hypoplasia in a few cases A cerebral and cerebellar lesion may coexist which is the reason for their classification as cerebrocerebellar diplegias

Aside from the congenital ataxias some of which are cerebellar others probably of cerebral type there are other forms of ataxia which have an acute onset and which persist during adolescence and adult life Batten has written informatively on this subject calling those forms the acute cerebellar ataxias of childhood Some are sequelae of an infection (a postinfectious encephalitis especially postvaricella) and a few may be due to virus infections which affect the cerebellum more than other parts of the nervous system Hyperthermia with temperatures over 106 F may result in extensive destruction of Purkinje cells and ataxia Cerebellar tumors and demyelinative and lipoid storage diseases also occur at this age and may at times give rise to cerebellar ataxia Labyrinthine injury resulting from streptomycin therapy and poly

unrecognized recurrent contusion of the spinal cord may result from handling the infant there being excessive mobility of the vertebral column If the upper cervical cord is severely damaged respirations may be difficult and signs of lower brain stem dysfunction may also appear Traction and stabilization of the cervical spine by orthopedic measures may prevent further damage and some improvement may occur but complete recovery is unusual with this condition

Similarly in *paraplegia* with weakness or paralysis limited to the legs the lesion may be cerebral or spinal Sphincter disturbances and a definite loss of somatic sensation below a certain level on the trunk should always favor a spinal localization Congenital cysts tumors and diastematomyelia are more frequently found in cases of paraplegia than of quadriplegia

The *etiology pathogenesis* and *morbid anatomy* of infantile cerebral hemiplegia bilateral hemiplegia and quadriplegia are not well understood Birth injury has been invoked as a leading cause and there is no doubt that prolonged labor delay in breathing bulging fontanel bloody cerebrospinal fluid periods of apnea and cyanosis occur with greater frequency in a series of hemiplegic infants than in any other group of infants Also birth injury is more frequent in hemiplegic than in diplegic cases The mechanism of the injury is not known In the majority of patients the birth trauma is not due simply to the direct application of force to the cerebral hemispheres Hypoxia due to cardiac arrest or interference with fetal circulation at the time when the brain was compressed may be responsible for the lesions The hemisphere opposite the hemiplegia may be small a veritable miniature of normal the cortex is thin depleted of nerve cells and gliotic and the thalamus and corticospinal tract are reduced in size In others a circumscribed encephalomalacia with shrinkage of convolutions gliosis or cavitation of white matter and basal ganglions have been found Central *lobar sclerosis* with destruction of the white matter and sparing of the cortex or multiple cavities in the white matter have been observed in a few cases It must be assumed that many of these abnormalities have been acquired during intrauterine life or at birth but their cause and pathogenesis are unknown They appear to represent forms of *pseudoporencephaly* Some may be due to narrowing or occlusion of the carotid artery (sometimes demonstrated in an arteriogram) or Sylvian vein Congenital neurosyphilis and toxoplasmosis have been established in others Prematurity may be a contributing factor and in some a history of vaginal bleeding during pregnancy has been recorded Developmental abnormalities of the brain have been discovered in a few cases

Congenital Extrapyramidal Syndromes in Infancy and Childhood The spastic and rigid cerebral diplegias discussed above shade almost imperceptibly into the extrapyramidal syndromes Many such cases can be found in every cerebral palsy clinic and they appear from time to time in adult medical clinics Pyramidal tract signs may be completely absent and the inexperienced student familiar only with the pure cerebral spastic diplegia syndrome is always puzzled as to their classification Some extrapyramidal cases of this type undoubtedly are attributable to the same pathologic processes as cerebral spastic diplegia and attest to the diverse clinical manifestations of these states others represent separate diseases such as erythroblastosis fetalis with kernicterus In the interest of being able to state accurately the probable pathologic basis and future course of these illnesses it is desirable to separate the extrapyramidal syndromes due to prenatal and natal diseases which usually become manifest during the first year of life from the acquired postnatal syndromes such as familial athetosis dystonia musculorum deformans and cerebellar ataxia The latter will be discussed in Chap 259 Degenerative Diseases of the Nervous System

Congenital Choreoathetosis (Double Athetosis) Probably the most frequent representative of this group this condition is like the spastic states in that it may not be recognized at birth but only after several months have elapsed The nature of chorea and athetosis has been discussed in Chap 26 Disturbances of the Motor System—Abnormalities of Posture Involuntary Movements All combinations of chorea athetosis hemiballismus and even dystonia may be found in a single case or one or another type of movement disorder may predominate However in all instances there is a defect in voluntary movement

Choreoathetosis in infants and children varies in severity In some the disorder is so mild that the abnormal movements are misinterpreted as restlessness or the fidgets in others every voluntary act is rendered ineffective by these involuntary movements leaving the patient nearly helpless The tongue may extrude itself from the mouth with constant drooling and the face is contorted in a never ending series of grimaces Speech is slurred inarticulate and punctuated by grunts and hideous throat sounds The hands and arms are engaged in a constant play of writhing twisting movements and all attempts to use the limbs result in a slow spreading spasm of the entire limb or all the musculature (intention spasm) Bizarre postures may be assumed The arms may be carried in a flexed or extended position in front of or behind the body and the legs may be extended The feet may be

ducted or extended posture This state of contracture of the limbs in infants is called *arthrogryposis* already referred to above It may be caused by either a primary muscular disease or a defect of the central nervous system

Brachial plexus palsies well known complications of dystocia usually result from forcible extraction of the fetus by downward traction on the shoulder in a breech presentation or from traction and tipping of the head in a shoulder presentation The upper brachial plexus and roots of the fifth cervical or the lower plexus and roots of the seventh and eighth cervical and first thoracic nerves suffer the brunt of the injury Sometimes the entire plexus is involved The upper plexus injuries (*Erb s plexus syndrome*) are estimated to be twenty times more frequent than lower (*Klumpke plexus syndrome*) according to Ford who has examined more than 200 cases of this type There should be no difficulty in distinguishing these plexus injuries from the preceding motor disorders The paralysis is restricted and complete The condition is nearly always unilateral though a few cases with bilateral involvement have been reported The infant with Erb s palsy lies in a characteristic position the affected arm is adducted and internally rotated at the shoulder and extended at the elbow The deltoid spinati biceps brachioradialis and upper pectoral muscles are paralyzed The diaphragm on the side of the palsy instead of descending with each inspiration moves paradoxically and the efficiency of pulmonary ventilation may be greatly reduced During spontaneous movements and in the Moro reflex the affected limb is motionless The grasp reflex is preserved in upper plexus injuries The biceps and supinator reflexes are absent and the triceps is present but one cannot count on these reflexes for they may normally be difficult to elicit In the Klumpke plexus injury the muscles of the hand and forearm are paralyzed whereas the function of the shoulder abductor and external rotators and elbow flexors is preserved The limb reposes in a flexed position across the trunk and the grasp reflex is absent There is often an associated Horner s syndrome The remainder of the musculature is active The pathology of these plexus injuries has not been carefully studied From the few reports it appears that the traumatic lesion involves motor roots at their junction with the brachial plexus In some cases the roots are virtually torn from the spinal cord and the matter may be damaged The treatment of Erb s palsy is immobilization of the affected arm in an abducted and flexed position Prognosis is good in the majority of cases but in severe injuries paralysis may be permanent in which instance the hand or arm fails to develop

Facial paralysis due to injury of the facial nerve immediately distal to its exit from the stylomastoid foramen by the application of forceps is another common peripheral nerve affection in the newborn The failure of one eye to close and the difficulty in suckling make this condition easy to recognize It must be distinguished from congenital facial paralysis or facial diplegia with or without weakness of the abducens muscles (*Moebius syndrome*) in which the facial nerve cells fail to develop In most cases of facial paralysis function is recovered after a few weeks in some the paralysis is permanent and may account for an asymmetry observed in later life

The Retarded Child (Feeblemindedness)

Mental retardation has been commented upon in the discussion of many of the craniospinal malformations and in the several varieties of cerebral palsy However it may also occur as the only neurologic abnormality and must therefore be discussed separately

To the pediatrician the clinical problem of mental retardation is one of the most difficult and to the parents it is one of the most dreadful of all conditions The intelligent father and mother are alert to every sign of possible brain injury and often they become alarmed about trivial deviations from their standard of normal development Slowness in sitting standing walking delay in speech any difficulty in acquiring toilet training may be seized upon as an indication of feeblemindedness The internist and general physician are apt to see only the milder noninstitutionalized patients who reach adolescence and adult years and then develop other diseases

The primary responsibility of the physician in cases of this type is to determine whether there is unmistakable evidence of maldevelopment or disease of the brain The uncertainty in evaluating cerebral function during early infancy has already been discussed From experience one learns that successive examinations over a period of months or years may be required in order to evaluate the infant s or child s capacity for mental development Above all the physician should not permit himself to be forced into a hasty or premature judgment Deafness blindness congenital speech defects (word deafness and word blindness) and motor defects must be searched for with particular care for they may account for an apparent delay in mental development by interfering with the learning processes Emotional privation and neglect may also lead to some degree of backwardness However mental retardation of significant degree cannot be explained in this way

The student confronted with a backward infant is likely to be rather bewildered by the vast array of developmental abnormalities and diseases which

neuritis or mumps are the common causes of non cerebellar ataxia which must be differentiated from the above condition

The hereditary ataxias are likely to begin at a later age and are progressive They are discussed in Chap 259

In all these congenital diseases of the brain once the symptoms and signs are well established there is no progression of the illness In fact with further maturation and training there may be improvement The clinical course thus distinguishes this whole group of diseases from those of delayed onset and progressive course (see Schilders disease lipoid storage diseases congenital neurosyphilis and toxoplasmosis which are described in Chaps 257 and 259)

The Flaccid Paralyses of Infancy and Childhood *The cerebral form first described by Foerster and called cerebral atonic diplegia* has already been mentioned in connection with congenital cerebellar ataxia It can usually be distinguished from spinal and peripheral nerve paralysis by the retention of postural reflexes (flexion of the legs at the knee and hip when the patient is lifted by placing the hands in the axillae) the preservation of tendon reflexes and the failure of mental development

The syndrome of *infantile muscular atrophy* (Werdnig Hoffmann disease) is the leading example of the category of infantile spinal muscular atrophies These little patients are usually brought to the clinic by their parents because of a difficulty with feeding and a delay of motor development About half of them are said to have been normal at birth and during the first weeks of life *Others have been slack feeble infants from the day* they were born and even before since some mothers recall a weakness also of fetal movement Slowness in feeding frequent choking constant drooling recurrent respiratory infections due to weak respiratory movements and aspiration of milk are troublesome in early life As a rule the patient prefers a supine posture his motor deficit is manifested by an inability to maintain the head in stable balance and also by the absence of the usual twisting squirming movements of the trunk The arms tend to be kept at the sides and flexed at the elbows bringing the hands over the chest The legs are characteristically abducted and flexed at the hips and knees so that the soles of the feet oppose one another (frog posture) When the infant is pulled to a sitting position the head lolls and all but the most feeble support reactions in the legs are absent Despite this profound weakness all muscle groups are capable of feeble movement until late in the course of the illness The tendon reflexes are invariably absent *Atrophy of muscle* is obscured by subcutaneous fat tissues (puppy fat) and fasciculár twitches though detectable in an electromyogram are invisible to the naked eye except in the tongue In contrast to their feeble movements these patients usually are attractive with bright sparkling eyes and lively countenance which attest to normal brain development All sensory functions are likewise retained The illness progresses slowly over a period of months or a few years and few of these patients survive until puberty Several members of a sibship may suffer the same illness but never the antecedents the pattern of inheritance usually being autosomal recessive In biopsy material or at autopsy the muscles are thin and the majority of their fibers are atrophic preserving their fetal dimensions as though improperly innervated or denervated The anterior horn cells in the spinal cord and brain stem have disappeared or are in process of degenerating and are replaced by fibrous astrocytes There is no known treatment for the disease

A few patients suspected of having infantile muscular atrophy prove with the passage of time to be merely rather inactive slack children and their motor development later proceeds at the usual rate A few may remain rather weak with thin musculature Such cases fall into the vague category of *amyotonia congenita* described by Oppenheim Brandt and others or into the group called *benign congenital hypotonia* (Walton) or *benign congenital myopathy* (Turner) Probably several types of myopathy are being included in this category Muscle biopsy usually reveals no definite abnormality and the electromyogram is often normal

Infantile muscular dystrophy and lipoid and glycogen storage diseases may also produce a clinical *picture of progressive atrophy and enfeeblement of* muscles The diagnosis of *glycogen storage disease* (von Gierkes disease) should be entertained when the syndrome of infantile muscular atrophy is associated with clinical enlargement of heart liver or spleen The motor disturbance in this condition may be related in some way to the abnormal deposits of glycogen found in skeletal muscle though it is more likely due to the degeneration of the anterior horn cells of the spinal cord which are distended with glycogen and other substances Lipoid storage disease of *Tay Sachs* and the variants which occur later in life may also cause thinness of limb musculature feebleness of movement and diminution or loss of tendon reflexes Regression of mental development blindness macular degeneration which are almost always present to some degree should leave little doubt as to the nature of the illness Also muscular dystrophy either familial or nonfamilial may begin during fetal life or during infancy and childhood There is obvious palsy of the limbs with proximal and trunk muscles more involved than distal ones Contractures are frequent with a leg or arm held in a curious ab

ganic driveness is perhaps more commonly observed in acquired postnatal encephalitis than with congenital diseases Rhythmic rocking rolling head banging and bouncing movements are common in retarded children and may be performed hour after hour often to the accompaniment of bleating sounds squeals and other ejaculations Here the abnormality is not the appearance of rhythmic movements of the body which are observed at one period in the development of many normal children but their persistence Music may encourage rhythmic movement and gives pleasure to many retarded children

The least severely retarded child (IQ 50 to 70) grows and develops in many ways not different from normal and he can be taught useful occupational skills A few can work under careful supervision

Special Varieties of Mental Retardation Several of the special types of mental retardation have already been discussed in this and other chapters (cf Lipoidoses and Cerebral Sclerosis in Chap 259) In the following pages are presented only those with special features

Mongolism This is a unique condition and although accounting for only about 1 per cent of all mental defectives it is the reason for one third to one half the admissions to state schools Mental retardation which varies from mild to severe a curious facial configuration with an Oriental cast to the eyes and a dwarfed physical stature constitute a clinical triad Many of the stigmas of mongolism can be recognized in the neonatal period The head tends to be small and oval with the forehead sloping The ears are set low on the scalp and are oval with small lobules The eyes slant slightly upward and outward owing to the presence of an epicanthal fold which covers the medial angle of the palpebral fissure The bridge of the nose is generally absent or poorly developed and the crest of the nose small The mouth tends to hang open and the tongue is usually enlarged heavily fissured and protruding Gray white specks of depigmentation are seen in the iris (Brushfield s spots) The little fingers are often short and curved owing to a hypoplastic middle phalanx The hands are broad and simianlike with a single transverse palmar crease Lenticular opacities and congenital heart lesions are found in some cases At birth the mongoloid child is of average size but at later periods of life he is characteristically small Benda estimates that the average adult person with mongolism of whom there are many never exceeds the stature of a ten year old boy The resemblance to the Oriental is at most superficial in fact the differences are so striking that it is quite easy to recognize the condition in those of Oriental heritage

The cause of mongolism is not known It has been suggested that the defects arise as a result of some metabolic abnormality which occurs late in the second or early third month of pregnancy Older mothers are more apt to have mongoloid babies than are young mothers The mean age of the mother at the time of birth of the mongoloid child is thirty seven It is thought by some workers that a genetic factor is responsible but familial incidence is rare Aside from a rather rounded brain which conforms to the shape of the skull a subnormal weight and a relatively simple convolutional pattern no abnormalities can be seen in the brain of the mongolian idiot Pituitary extracts of doubtful potency have been used in treatment but the results are impossible to evaluate

Cretinism This is due to congenital deficiency of thyroid secretion and is distinguished from myxedema a form of hypothyroidism acquired later in life It develops most often in areas where goiter is endemic The typical symptoms and signs are usually recognized between the sixth and twelfth months of life when retardation of growth and the curious alterations in physical appearance first appear The thick lips the puffy eyelids the short wrinkled forehead with low hair line the broad nose the open mouth with large protruding tongue the pale mucous membranes the dry skin and the coarse scanty hair comprise a highly distinctive picture Also it is to be noted that the body is small the limbs are short and there is a protuberant abdomen There are prominent fat pads above the clavicles in the axilla and between the shoulder blades The temperature tends to be subnormal and the pulse slow These findings usually distinguish the cretinoid from the mongoloid or gargoyloid child with whom he may be confused X rays are an additional aid for they show that the centers of ossification are delayed in their development The carpal and tarsal bones may not appear until the tenth year The tendon reflexes are of small amplitude and prolonged Intelligence is nearly always impaired Many cretins never learn to talk or at most may say only a few words Standing walking and all actions are retarded Their disposition is remarkably amiable In a few of the reported cases there has been cerebral diplegia The protein content of the cerebrospinal fluid is often elevated The pathologic anatomy of the brain disease is poorly described no thorough studies of it have been made In the authors material inadequate though it is no convincing histologic changes have been found Once cretinism has fully developed thyroid replacement is of no value A premium must therefore be placed on early diagnosis for thyroid replacement therapy during the first year of life may result in marked improvement Even then normal mentality may not be attained because it is said of an associated developmental abnormality of the brain

may affect the brain at an early age and prevent normal mental development It becomes necessary to acquire a way of thinking about these problems The authors bedside approach has been to attempt to categorize each case according to the scheme presented below This can be done by obtaining the necessary clinical data—a careful history in order to determine whether or not the condition is progressive and a physical examination in which one searches for evidences of cranial skeletal ectodermal cardiac and other developmental abnormalities Once a patient is categorized it is less difficult to decide which of several diseases is present

CLINICAL CLASSIFICATION OF THE VARIETIES OF NONPROGRESSIVE MENTAL RETARDATION

I Mental defect with associated developmental abnormalities in nonnervous structures
  - *A* Those affecting cranioskeletal structures
    1. Microcephaly
    2. Macroencephaly
    3. Hydrocephalus
    4. Craniostenosis
    5. Morquio s disease
    6. Gargoylism
    7. Mongolian idiocy
    8. Cretinism
    9. Cleidocranial dysostosis
    10. Achondroplasia
    11. Gonadal dysgenesis (Bonnaire Ullrich Turner syndrome)
  - *B* Those affecting nonskeletal structures
    1. Phakomatoses (tuberous sclerosis von Recklinghausen s disease Sturge Weber syndrome etc)
    2. Ectodermal dysplasia
    3. Congenital heart disease
    4. Deafness and congenital heart disease following maternal rubella

II Mental defect without developmental anomalies in nonnervous structures but with focal cerebral and other neurologic abnormalities
  - *A* Cerebral spastic diplegia with or without involuntary movements
  - *B* Cerebral hemiplegia unilateral or bilateral
  - *C* Congenital choreoathetosis or ataxia
    1. Kernicterus
    2. Status marmoratus (hypoxia?)
  - *D* Congenital atonic diplegia
  - *E* Rarely with other inherited neuromuscular abnormalities (muscular dystrophy Friedreich s ataxia etc)

III Mental defect without signs of other developmental abnormality or neurologic disorder
  - *A* Simple mental retardation
  - *B* Kernicterus
  - *C* Hypoxia
  - *D* Phenylpyruvic oligophrenia } These may be progressive
  - *E* Galactosemia }
  - *F* Heller s disease }

A number of progressive neurologic diseases—chronic subdural hematoma neurosyphilis toxoplasmosis lipoidoses and cerebral scleroses—may be confused with these static defects

Clinical Characteristics As an aid to the general physician who must undertake the diagnosis and management of backward children the following comments may be of some value Mental retardation manifests itself in the spheres of motor language social and intellectual development The severely retarded child at idiot level with an Intelligence Quotient (IQ) of less than 20 and unable to look after himself often does not sit up walk or stand and if any of these motor activities are acquired they appear late and are imperfectly performed Language is not mastered or at most only a few words are understood and uttered Physical growth is usually retarded nutrition may be poor and susceptibility to respiratory infections is common Sphincteric control is never accomplished Most of these severe aments never learn to dress bathe or feed themselves or to use implements and common tools Physical deformities are common in this group and they always suggest that the brain disease began in the antenatal period because of either a genetic disorder or a disease which occurred during the first 12 weeks of pregnancy Affections of the nervous system which have their onset later in life are usually not attended by bodily disfigurement

If the mental defect is less pronounced with the IQ 20 to 50 (i e imbecile) or 50 to 70 (i e moron) and if specific motor defects do not coexist then sitting walking and speech are acquired but only after a delay in many cases The existence of a cerebral defect may be noted for the first time when the child fails to speak normally during the second and third years of life and seems not to be able to learn the usual household tasks as well as other children However delay in language development must not by itself be taken as a mark of mental retardation for many bright children who are obviously intelligent and who show remarkable talent in communicating by gesture are slow in talking Toilet training also may be difficult to accomplish in the retarded child but again it may be delayed in an otherwise normal child because of incorrect parental attitudes and emotional problems The appearance of these retarded children is revealing for many have a dull apathetic appearance and their motor activity may be either reduced or excessive Some are very docile and affectionate others display a curious inquisitiveness irritability and destructiveness The most extreme degree of this overactivity is seen in the patient with "organic driveness a term introduced by Eugene Kahn to designate the incessantly moving incorrigible child who strikes at or bites every person or object which thwarts him in any way and who demolishes every object which he can reach Some of these children seem strangely impervious to injury and neither reward nor punishment influences them This or

ganic driveness is perhaps more commonly observed in acquired postnatal encephalitis than with congenital diseases Rhythmic rocking rolling head banging and bouncing movements are common in retarded children and may be performed hour after hour often to the accompaniment of bleating sounds squeals and other ejaculations Here the abnormality is not the appearance of rhythmic movements of the body which are observed at one period in the development of many normal children but their persistence Music may encourage rhythmic movement and gives pleasure to many retarded children

The least severely retarded child (IQ 50 to 70) grows and develops in many ways not different from normal and he can be taught useful occupational skills A few can work under careful supervision

Special Varieties of Mental Retardation Several of the special types of mental retardation have already been discussed in this and other chapters (cf Lipoidoses and Cerebral Sclerosis in Chap 259) In the following pages are presented only those with special features

Mongolism This is a unique condition and although accounting for only about 1 per cent of all mental defectives it is the reason for one third to one half the admissions to state schools Mental retardation which varies from mild to severe a curious facial configuration with an Oriental cast to the eyes and a dwarfed physical stature constitute a clinical triad Many of the stigmas of mongolism can be recognized in the neonatal period The head tends to be small and oval with the forehead sloping The ears are set low on the scalp and are oval with small lobules The eyes slant slightly upward and outward owing to the presence of an epicanthal fold which covers the medial angle of the palpebral fissure The bridge of the nose is generally absent or poorly developed and the crest of the nose small The mouth tends to hang open and the tongue is usually enlarged heavily fissured and protruding Gray white specks of depigmentation are seen in the iris (Brushfield s spots) The little fingers are often short and curved owing to a hypoplastic middle phalanx The hands are broad and simianlike with a single transverse palmar crease Lenticular opacities and congenital heart lesions are found in some cases At birth the mongoloid child is of average size but at later periods of life he is characteristically small Benda estimates that the average adult person with mongolism of whom there are many never exceeds the stature of a ten year old boy The resemblance to the Oriental is at most superficial in fact the differences are so striking that it is quite easy to recognize the condition in those of Oriental heritage

The cause of mongolism is not known It has been suggested that the defects arise as a result of some metabolic abnormality which occurs late in the second or early third month of pregnancy Older mothers are more apt to have mongoloid babies than are young mothers The mean age of the mother at the time of birth of the mongoloid child is thirty seven It is thought by some workers that a genetic factor is responsible but familial incidence is rare Aside from a rather rounded brain which conforms to the shape of the skull a subnormal weight and a relatively simple convolutional pattern no abnormalities can be seen in the brain of the mongolian idiot Pituitary extracts of doubtful potency have been used in treatment but the results are impossible to evaluate

Cretinism This is due to congenital deficiency of thyroid secretion and is distinguished from myxedema a form of hypothyroidism acquired later in life It develops most often in areas where goiter is endemic The typical symptoms and signs are usually recognized between the sixth and twelfth months of life when retardation of growth and the curious alterations in physical appearance first appear The thick lips the puffy eyelids the short wrinkled forehead with low hair line the broad nose the open mouth with large protruding tongue the pale mucous membranes the dry skin and the coarse scanty hair comprise a highly distinctive picture Also it is to be noted that the body is small the limbs are short and there is a protuberant abdomen There are prominent fat pads above the clavicles in the axilla and between the shoulder blades The temperature tends to be subnormal and the pulse slow These findings usually distinguish the cretinoid from the mongoloid or gargoyloid child with whom he may be confused X rays are an additional aid for they show that the centers of ossification are delayed in their development The carpal and tarsal bones may not appear until the tenth year The tendon reflexes are of small amplitude and prolonged Intelligence is nearly always impaired Many cretins never learn to talk or at most may say only a few words Standing walking and all actions are retarded Their disposition is remarkably amiable In a few of the reported cases there has been cerebral diplegia The protein content of the cerebrospinal fluid is often elevated The pathologic anatomy of the brain disease is poorly described no thorough studies of it have been made In the authors material inadequate though it is no convincing histologic changes have been found Once cretinism has fully developed thyroid replacement is of no value A premium must therefore be placed on early diagnosis for thyroid replacement therapy during the first year of life may result in marked improvement Even then normal mentality may not be attained because it is said of an associated developmental abnormality of the brain

Gargoylism (Hunter Hurler Disease) A metabolic abnormality which affects the brain the cranial bones and skeleton and the internal organs (liver spleen heart lungs and blood) this disease appears in families apparently being determined by an autosomal recessive gene The symptoms and signs usually become manifest during the early years of life The appearance of the patient is most striking and will alone permit diagnosis The head is slightly enlarged dolichocephalic or scaphocephalic with rather shallow orbits and protruding eyes and forehead The bridge of the nose is depressed and the eyes widely spaced The lips are thick and the tongue seems too large for the mouth interfering somewhat with breathing Breathing is rather noisy as though the oropharynx and mouth were partially obstructed The cornea has a steamy or cloudy appearance Growth is stunted and most patients are dwarfs The neck and trunk are usually short and the vertebrae malformed A kyphotic deformity of the thoracic spine is a frequent finding The extremities are short and the hands and feet broad and spadelike Many of the joints are ankylosed The abdomen protrudes to allow room for the enlarged liver Mental development may be normal or retarded to a variable degree Hydrocephalus may occur Granules of a material that takes a glycogen stain have been seen in neutrophilic leukocytes in the circulating blood Postmortem examination has shown the nerve cells to be swollen with inclusion material which chemical analysis shows to be a ganglioside like that found in the nerve cells of Tay Sachs infantile Gaucher s and Niemann Pick diseases There are also fat laden macrophages in the perivascular spaces and in the meninges both macrophages and an increase in fibrous tissue Glycogen and a peculiar lipoprotein material are also found in liver cells and the Kupffer cells and macrophages in a fashion reminiscent of von Gierke s disease The skeletal abnormality is said to be an osteochondrodystrophy The disease is progressive and fatal within a few years in most instances There is no treatment

Osteochondrodystrophy (Morquio s Disease) Sometimes confused with gargoylism this is a nonprogressive osseous disorder with a cranial appearance similar to that of gargoylism Some patients have a normal mind others have a stationary mental defect but in the latter none of the typical brain lesions of gargoylism have been found and the nature of the anatomic defect remains unknown No visceral lesions have been observed The primary defect is believed to be one of the chondroblasts

Phenylketonuria (Phenylpyruvic Oligophrenia) This condition is discussed in Chap 92 Disorders of Amino Acid Metabolism to which the reader is referred for the biochemical findings Jervis has estimated that 1 in 25 000 people in the United States has the disease It has been observed in individuals of Mediterranean Scandinavian and Irish origin and has seldom been seen in Jews and Negroes Characteristically the affected person is of light complexion with blue eyes but a few have been of darker complexion The lightness of complexion is thought to be due to a defect in pigment metabolism Those with the lighter coloring are said to have a lower intelligence Some patients are of small stature and the circumference of the head may be subnormal The mental defect is generally not recognized for some months or years after birth and appears to be progressive The degree of retardation varies from mild to severe Seizures occur in approximately 20 per cent of cases There are usually no associated neurologic symptoms and signs There are no consistent histopathologic changes in the brains of uncomplicated cases If the diagnosis is made early the administration of a diet low in phenylalanine is said to have resulted in clinical improvement

Galactosemia Another congenital metabolic disease galactosemia is thought to be transmitted by a single autosomal recessive gene It is characterized clinically by mental defect cataract nausea vomiting hepatomegaly jaundice and the excretion of large quantities of galactose in the urine The biochemical defect is discussed in Chap 94 The manner in which galactosemia induces the symptoms and signs of the neurologic disorder is not known No pathologic studies are available The infants are normal at birth but on the usual milk diet develop signs of malnutrition nausea and vomiting Soon the other symptoms develop The diagnosis should be suspected whenever reducing substances are present in the urine of retarded children There are however no ketone bodies and acidosis does not occur Galactose can be identified by paper chromatography or by the formation of a specific osazone Aminoaciduria and abnormally flat glucose tolerance curves are helpful diagnostic laboratory findings Hypoglycemia may be found and aggravated temporarily by the injection of galactose Replacement of milk in the diet with its high content of galactose is said to result in clinical improvement

Anhidrotic Ectodermal Dysplasia This is a congenital disorder in which there are anhidrosis defects in salivation lacrimation sparse hair and faulty dentition Heat intolerance with paroxysmal fever unrelated to infection may occur Several of the reported cases have been feebleminded A sex linked inheritance pattern has been reported The neuropathologic basis for this disease is unknown There is no treatment

Heller s Disease (Dementia Infantilis) This condition is of uncertain status Neurologists and some

psychiatrists look upon it as a cerebral disease of undetermined cause Other psychiatrists believe it to be a form of precocious schizophrenia As a rule the onset is in about the third or fourth year of life At this age usually without previous illness a change in character is noted Irritability negativism disobedience and outbursts of unprovoked temper become manifest Restlessness and destructiveness are other prominent symptoms Toys with which the child had played normally are now senselessly destroyed Within a few months there is complete loss of speech and also failure in the understanding of words Grimacing and ticlike movements appear but motor and sensory functions are preserved Continence of sphincters is lost The mental regression continues to a stage of idiocy but all through the illness the patient continues to give an impression of greater intelligence than do most feebleminded individuals Many patients of this type reach adult life but remain in institutions The pathology of the disease is unknown A few of the reports state the brain to be abnormal and suggest that there may be degeneration of ganglion cells like that of Tay Sachs disease but the illustrations are unconvincing There is no treatment The relationship of this disease to many cases of so called childhood schizophrenia" is not always clear It is said that the patient with childhood schizophrenia although withdrawn and mute maintains an inquisitive interest in his surroundings and is clever in handling tools and in manipulating objects

Simple Mental Retardation Although presented last this category includes the great bulk of children with mental defect of indeterminate etiology who exhibit neither craniovertebral nor neurologic abnormality The degree of mental impairment tends to be mild (moron feebleminded educable) or moderate (imbecile trainable) Penrose found that this group of aments comprised 24 per cent of 1 280 institutionalized children and of course those who are in institutions represent only the more severely damaged individuals in our society The physical appearance of these children is usually not strikingly abnormal yet many of the afore mentioned characteristics of the mentally retarded child are to be observed Seizures occur in a significant number being several times more frequent than in a normal population Within the limits of their intelligence the success of these children in learning to look after themselves is often determined by the effectiveness of their teachers and the suitability of the environment in which they are placed The brighter ones can profit to some extent from formal education Those less well endowed may be trained to care for their personal wants and needs and may profit from a limited amount of manual training Special schools and classes are of great help

Society in the final analysis determines the eventual disposition of these unfortunates Many of them being not unattractive and giving less trouble than many other defective children may adjust to foster families and live in a community They need protection for they are easily led astray and may commit infractions of the law usually of a minor sort Sexual offenses are common in the girls Institutionalization is required when family and society cannot or do not wish to look after them Reproductivity is frequently impaired in those with severe mental defect but may be distressingly undisturbed in many of the less defective individuals

The problem of eugenics assumes great importance This type of mental defect is often seen in families where one or both parents are dull or retarded The term *familial* may be applied to this group However the majority of cases are sporadic Probably there are multiple etiologic factors which may lead to simple mental retardation The pathology is variable ranging from "no demonstrable lesion" to several different gross and microscopic abnormalities

Management of the Retarded Child and His Parents It is an unpleasant task to inform parents that their child is abnormal in any respect and many if not most parents find it difficult to accept a mental defect without much self recrimination and feeling of guilt To give an honest statement of the degree of the child s retardation and based on the nature of the problem some professional estimate of the likelihood of future growth and development once one is sure of the status and potentialities of the child requires tact and sympathetic understanding The family must eventually be told to what extent the child is likely to be trainable or educable Obviously this can often be no more than an educated guess and if there is still reasonable doubt about the future this fact should be so stated In general it should be possible to give at least a rough approximation of the child s capabilities and likely attainments Frequently the parents themselves are well aware of the child s limitations and then a useful technique is to ask the parents to estimate the nature of the problem The physician is in this way informed of the degree of their insight and their general attitudes He may then agree with them or may amplify and clarify any misconceptions

The parents will want to know the probable cause of the defect and the likelihood of subsequent children being affected In most instances the answer to the second question will depend on the etiology If the abnormality is determined by known genetic factors as in congenital microcephaly phenylpyruvic oligophrenia or tuberous sclerosis there is of course a strong likelihood of other children being abnormal If on the other hand the abnor

mality is due to specific environmental influences peculiar to the pregnancy as in the case of maternal rubella or excessive radiation to the pelvis the prospects of having other normal children are good Unfortunately in the great majority of cases the etiology will not be clear and advice must be tendered cautiously It is quite clear from the studies of Penrose Halperin and others that the chance of parents of normal intelligence with one defective child having other subnormal children is greater than that of the general population If one or both parents is of less than normal intelligence or if there is consanguinity in the parents then the risk is considerably greater A recessive trait in a first child which is inherited in only one of four children and cannot be passed on in overt form to succeeding generations need not discourage a family from "taking a chance on having other normal children

Special Paroxysmal Disorders of Nervous Function in Infancy and Childhood

The convulsive disorders have been discussed in Chap 35 *Recurrent Convulsions* and all that was said there applies to infants and children as well as adults There are however many special problems raised by the child who is having spells or seizures and these must be known and properly interpreted by the physician who upon seeing the patient at a more advanced age obtains the history of these spells

The incidence of convulsions is known to be high in infancy and early childhood and seizures at that age may have an altogether different significance than in the adult All the seizure patterns that may be witnessed in the adult may also occur in infancy and childhood—i e focal motor and Jacksonian as well as petit mal and psychomotor seizures—but certain ones appear at this age which are not often observed in the adult These are the petit mal and its variants and massive myoclonus Then too there are other types of spells unique to infancy and childhood which must be distinguished from convulsions i e breath holding spells and the congestive attacks that accompany congenital heart disease

Seizures have different meanings at different periods of infancy and childhood A series of seizures that occurred during the neonatal period must always be regarded as an omen of cerebral damage It may have been due to subdural and subarachnoid hemorrhage in which unresponsiveness pallor periods of apnea bulging fontanel and grossly bloody cerebrospinal fluid clarify the diagnostic problem It may reflect a congenital brain disease sometimes of such major proportions as to have prevented further development or it may have been so slight as not to disturb the normal maturation processes Actually very little is known of the import of seizures at this period with reference to prognosis for mental development Infantile tetany during the first 2 to 3 weeks of life may have been the cause of seizures as well as of a remarkable stiffness of limbs and carpal spasms (The Chvostek sign is misleading at this age being present in many normal babies) Only the blood calcium and phosphorus levels and the response to intravenous calcium would have confirmed the diagnosis A single outburst of seizures in a previously healthy infant may have been merely an expression of the low convulsive threshold of the infantile nervous system as in febrile convulsions or may signify a mortal process such as the water intoxication syndrome acute toxic encephalopathy thrombosis of the superior sagittal sinus or cerebral veins meningitis hypoglycemia brain hemorrhage from an angioma or massive arterial infarction Idiopathic epilepsy also begins during infancy and childhood and may interfere relatively little with normal development Brain tumors are an infrequent cause of seizures during infancy and childhood

Febrile Fits

Certain infants and children are disposed to convulsions with fever Lennox estimates that approximately 2 per cent of all children have one or more convulsions with fever at one time or another during infancy or childhood In some 20 per cent of these cases it can be decided in retrospect that fever has served merely to precipitate a seizure in an individual who has suffered a cerebral disease or who has idiopathic epilepsy Such individuals will continue to have seizures unassociated with fever In the other 80 per cent of cases seizures occur only during febrile episodes and never recur beyond early childhood The reason for this low seizure threshold in the infantile brain is unknown but a family history of similar febrile fits in other members of the family can be obtained in about 50 per cent of cases

From the history it can usually be learned that febrile convulsions have occurred between the ages of one and three years only a few cases are seen earlier or later—up until the age of seven or eight years Any febrile illness may have been provocative but usually a rapid ascent of temperature to 103 F or higher was responsible The seizures themselves are generalized and of short duration and may have occurred singly or in a cluster of two or three The postictal coma is of short duration No record of focal or lateralizing neurologic signs can be obtained The cerebrospinal fluid is clear and acellular and the total protein normal The EEG is diffusely abnormal with theta and delta waves predominating in all leads immediately after the seizure with rapid return to normal at

the termination of the illness After the illness there should be no residual signs of brain disease

It must be remembered that there are certain sources of error in the diagnosis of febrile convulsions The fever may have been caused by convulsions as so often happens in idiopathic epilepsy especially with status epilepticus Some primary inflammatory disease of the brain or meninges may have been responsible for both fever and convulsions Meningitis for example may have begun in this way but would probably have ended fatally if not diagnosed and treated

Massive Myoclonus

This syndrome known also by the names *infantile muscular spasm Blitzkrampf myoclonic seizure* Salaam fit" flexor spasm and "jackknife seizure has been recognized recently and should be known to general physicians and internists for they may see the patient long after the seizures have stopped In essence it is a sudden synchronous contraction of many muscle groups Contraction of flexor muscles usually predominates and there is a sudden flexion of trunk neck and extremities often accompanied by a cry or occasionally by a laugh In some patients there is a combination of flexor and extensor movements and least often the contraction of extensor muscles predominates with a straightening of the body and a fall backwards The spasm itself is usually momentary but often recurs one or several times with each spasm separated from the next by an interval of a few seconds There may be only a few spasms in a cluster or upwards of a hundred or more in a series They are especially frequent as the patient is falling off to sleep or upon awakening The patient may fall if he is standing at the time of the spasm Sensory precipitation by handling feeding noise and fever have been noted

Massive myoclonic spasms usually begin during the first few months of life and tend to disappear or to be replaced by other seizure patterns between the second and third years of age The pathophysiology is not well understood and the neuropathology of the condition has not been studied systematically The frequent association of mental retardation (over half the cases) and the consistent diffusely abnormal electroencephalogram with bursts of high voltage slow waves referred to as *hypsarrhythmia* by Gibbs suggest a diffuse neuronal pathology It is of interest that the seizures may become less frequent as the dementia progresses

In early life parents may mistake the flexor spasm for colic This is especially true when feeding is a precipitating stimulus Colic however is never associated with even a transient loss of consciousness Associated seizure phenomena such as rolling up of the eyes and pupillary dilatation may be helpful points In the young infant this condition may also be confused with the Moro reflex but such an error is avoided if one gives attention to the precipitating sensory stimulus which is different in the two conditions and to the movements which usually occur in series Nevertheless the similarity of the movement pattern suggests that massive myoclonus and the Moro response probably both *utilize the same physiologic mechanisms*

The treatment of the seizures is difficult Some respond dramatically to the first drug tried but soon become resistant to it Diamox alone or in combination with phenobarbital has proved to be the most useful drug in the authors experience

"Breath holding Spells"

This is a special type of attack peculiar to young children and should have no significance in later life unless it becomes the basis of a psychologic problem Anger or a mild injury is the precipitating factor The patient begins to cry or scream After a few moments he suddenly stops breathing and remains apneic for many seconds to as long as a minute During this period there is a color change from an initial redness to cyanosis presumably as the result of hypoxia If this persists for a short period the patient suddenly becomes limp and is unresponsive for some seconds Convulsive twitching may occur but rarely is there a sustained convulsion The whole attack is over in from one to a few minutes The child may then be drowsy and sleep for a short while thereafter or may be at once as alert as before Such attacks usually begin late in the first year of life and rarely after the third year They are outgrown so to speak The mechanism is unclear in breath holding the infant may perform the Valsalva maneuver and then faint as in tussive syncope The treatment consists of reassurance and a careful explanation of the spells to the family It should be pointed out that in certain instances a child may seem to use" the attacks to obtain what he wishes and that by ignoring them they may be eliminated or reduced in number

Apnea may be observed as a fragment of a generalized seizure and must be differentiated from breath holding The sequence of events is so characteristic in breath holding that the diagnosis is usually not difficult

Congestive Attacks with Congenital Cardiac and Pulmonary Disease

This condition has been described only recently and is of importance in the histories of cases of congenital heart disease Cyanotic infants and children with gravely limited cardiopulmonary function may upon some unusual exertion or excitement or while crying momentarily lose consciousness and twitch a few times Presumably the spell depends

on hypoxia or inadequacy of cerebral blood flow It must be distinguished from seizures which occur with a higher than normal frequency in patients with congenital heart disease

Hypoglycemia

As stated in Chap 33 Coma and Related Disturbances of Consciousness hypoglycemia may cause seizures and unresponsiveness but as a rule the seizure does not interrupt a normal state of consciousness An unexpected convulsion is almost never due to hypoglycemia alone When this state is encountered in infants it is sometimes traceable to a hepatic form of glycogen storage disease in which there is an inherited defect of an enzyme system necessary in the synthesis or breakdown of glycogen These children tend to be obese Hepatomegaly and splenomegaly are important clinical features The failure of epinephrine to produce a significant rise in the blood sugar levels is diagnostic of glycogen storage disease Treatment consists of a regular diet supplemented by carbohydrate about 45 min after each meal to offset the fall in blood sugar

Older children are prone to attacks of idiopathic hypoglycemia They tend to be thin rather than obese and the attacks occur on a background of relatively poor intake of food or actual fasting for 12 to 36 hr Occasionally the child has engaged in unusually strenuous and prolonged exercise prior to an attack The mechanism is not clearly understood but depletion of glycogen stores and lack of available sugar due to fasting have been suggested The symptomatology is fairly characteristic The child is noted to be apathetic or mentally dull and pale Vomiting occurs early and there may be a complaint of hunger despite the vomiting If no food is ingested stupor coma or convulsions may develop The seizures tend to consist of irregular poorly synchronized twitchings that may shift from side to side They may continue for long periods A well circumscribed isolated convulsion however is uncommon

Hypoglycemia as a result of hypopituitarism Addison s disease and renal glycosuria as in the de Toni Fanconi syndrome is occasionally seen in children Pancreatic adenomas are rare in this age group

CONCLUSION

A knowledge of these special neurologic problems of infancy and childhood is of value to the student as well as to the general physician or internist it enables him to understand the nature of such illnesses when they are encountered in adults and permits better evaluation of their role in any new illness Also the habit of making observations on the level of native intellectual endowment is of importance The histories given by patients with neurologic problems must always be carefully checked against an outside source in planning for therapy one must always enlist the aid of the responsible member of the family or if the patient is institutionalized of the nurse or attendant Finally problems in eugenics are likely to arise and the physician is often asked to advise the family or health agencies in the community on such matters Accurate diagnosis and a carefully established genealogy usually permit a separation of a genetic from an acquired disease and are of some value in predicting the occurrence of such diseases in the progeny of the afflicted individual

254 CEREBROVASCULAR DISEASES

C Miller Fisher, Herbert R Karp and Raymond D Adams

Vascular diseases of the nervous system rank first among all the diseases of the nervous system The recognition of this fact and of the need of careful investigation of the causes and mechanisms of these diseases has aroused increasing interest in this subject in the past few years and for the first time the common stroke case is being made the object of systematic study Furthermore it is evident to all who work in this field of medicine that the cerebrovascular diseases provide one of the best approaches to the study of neurology No other group of diseases creates with such precision a localized brain lesion of comprehensible type and permits a nervous disorder to unfold with such clarity In past times the neurologist in attempting to learn the secrets of the function of the human brain has depended heavily on the focal ischemic lesion and there is no reason to doubt that cerebrovascular diseases will continue to offer instructive examples of disorders of nervous function the assiduous study of which will be well repaid

Every neurologic disease may be said to involve the vasculature of the nervous system in one way or another and it is necessary at the very outset to delineate the boundaries of the subject The term *cerebrovascular disease* is intended here to denote any disease in which one or more of the blood

vessels of the brain is primarily implicated in a pathologic process By pathologic process is meant any abnormality of the vessel wall an occlusion by thrombus or embolus rupture of a vessel a failure of cerebral blood flow due to a fall in blood pressure a change in the caliber of the lumen altered permeability of the vascular wall or increased viscosity of the blood The pathologic process within the vessel can be described not only according to its grosser aspects—thrombosis embolism rupture of a vessel etc —but also in terms of the more basic vascular disorder i e atherosclerosis hypertensive arteriolosclerosis arteritis trauma aneurysm developmental malformation etc Furthermore in classifying cerebrovascular diseases it is not sufficient to consider only the primary vascular lesion but equal weight must be given the resulting parenchymal changes The e pathologic effects in the brain are of two types ischemia with or without infarction and hemorrhage Aside from these the vascular lesion is silent the only exceptions being the local pressure effects of an aneurysm vascular headache (migraine hypertension arteritis) and occasionally increased intracranial pressure as in hypertensive encephalopathy and venous thrombosis

CLASSIFICATION

The following classification[1] is somewhat unorthodox and requires a few words of explanation First, in order to give the student an idea of the scope of this field the classification includes all the cerebrovascular diseases listed chiefly according to the parenchymal changes but also when indicated according to the primary vascular changes The common diseases and the common pathologic conditions are indicated in heavy type in order that they will not be lost among relatively rare or less important conditions Secondly this arrangement traces the steps followed by the clinician in reaching a clinical diagnosis in other words it outlines the clinical approach Lastly the classification is intended to serve the pathologist who also proceeds in his investigations by first determining the nature of the parenchymal lesion i e infarction or hemorrhage and then by seeking evidence of the underlying vascular disorder

It will be seen that there are nine major categories I Cerebral Infarction II Transient Cerebral Ischemia without Infarction III Intracranial Hemorrhage IV Vascular Malformations V The Arteritides VI Hypertensive Encephalopathy VII Dural Sinus and Cerebral Vein Thrombosis VIII Strokes of Undetermined Origin and IX Vascular Diseases without Changes in the Brain

Four principal conditions account for the majority of cerebrovascular lesions cerebral infarction due to atherosclerotic thrombosis (40 per cent) cerebral infarction due to embolism (25 per cent) hypertensive intracerebral hemorrhage (20 per cent) and ruptured saccular aneurysm or angioma (8 per cent) These four conditions occupy prominent places under Infarction (I) and Hemorrhage (III) Cerebral Ischemia without Infarction is given a separate nosologic position because of its clinical importance and therapeutic implications Vascular Malformations (IV) the Arteritides (V) and Venous Thrombosis (VII) are diagnostic entities of such distinctive attributes as to merit separate classification Hypertensive Encephalopathy (VI) represents a unique pathologic process and warrants a separate niche Strokes of Undetermined Origin (VIII) and a list of the Primary Vascular Diseases (IX) complete the classification

- I Cerebral infarction (pale red (hemorrhagic) and mixed types)
  - A Thrombosis with atherosclerosis
  - B Embolism
    - 1 Cardiac origin
      - a Atrial fibrillation and other arrhythmias (with rheumatic atherosclerotic hypertensive congenital heart disease)
      - b Myocardial infarction with mural thrombus
      - c Acute and subacute bacterial endocarditis
      - d Heart disease without arrhythmia or mural thrombus (mitral stenosis, etc)
      - e Complications of cardiac surgery
      - f Nonbacterial thrombotic ("marantic") endocardial vegetations
      - g Paradoxic embolism with congenital heart disease
    - 2 Noncardiac origin
      - a Atherosclerosis of aorta and carotid arteries (mural thrombus atheromatous material)
      - b From sites of cerebral artery thrombosis
      - c Thrombus in pulmonary veins
      - d Fat
      - e Tumor
      - f Air
      - g Complications of neck and thoracic surgery
      - h Miscellaneous rare types
      - i Of undetermined origin
  - C Other conditions causing cerebral infarction
    - 1 Ruptured saccular aneurysm

[1] This classification was drawn up by an ad hoc committee of the National Institute of Neurological Diseases and Blindness and will be included in the Transactions of the Second Princeton Conference on Cerebral Vascular Diseases to be published for the American Heart Association by Grune & Stratton in 1958

[2] These data are the result of a neuropathologic study by one of us (CMF) of 4x2 unselected autopsies

2 Cerebral venous thrombosis
3 Systemic hypotension
4 Complications of arteriography
5 Arteritis (see V)
6 Hematologic disease (polycythemia sickle cell disease thrombotic thrombopenia etc)
7 Dissecting aortic aneurysm
8 Trauma to carotid
9 Hypoxia
10 Radioactive or x ray radiation
11 With tentorial foramen magnum and subfalcial herniations
12 Miscellaneous rare types (e g migraine)

D Cerebral infarction of undetermined cause

II Transient cerebral ischemia without infarction

A Recurrent cerebral ischemic attacks (previously called vasospasm usually associated with atherosclerosis and thrombosis)

B Systemic hypotension (i e simple faint acute blood loss myocardial infarction Stokes Adams syndrome traumatic and surgical shock sensitive carotid sinus severe postural hypotension)

1 With focal neurologic deficit
2 With syncope

C Migraine

III Intracranial hemorrhage (including intracerebral subarachnoid and ventricular rarely subdural)

A Hypertensive intracerebral hemorrhage
B Ruptured saccular aneurysm (if unruptured see IV*A*)
C Angioma (if unruptured see IV*B*)
D Trauma
E Hemorrhagic disorders (leukemia aplastic anemia thrombopenic purpura liver disease complication of anticoagulant therapy hyperfibrinolysis etc)
F Hemorrhage of undetermined cause (normal blood pressure and no angioma)
G Hemorrhage into primary and secondary brain tumors
H Septic embolism mycotic aneurysm
I With hemorrhagic infarction arterial or venous (see under I and VII)
J Secondary brain stem hemorrhage (temporal lobe herniation)
K Hypertensive encephalopathy
L Idiopathic brain purpura
M With inflammatory disease of arteries and veins (see under V VII)
N Miscellaneous rare types

IV Vascular malformations and developmental abnormalities

A Aneurysm—saccular fusiform globular diffuse (if ruptured see III*B*)
B Angioma [including familial telangiectasia trigeminal encephaloangiomatosis of Sturge Weber Dimitri and retinal pontine hemangiomas (if ruptured see III*C*)]
C Absence hypoplasia or other abnormality of vessels (including variations in pattern of circle of Willis)

V Inflammatory diseases of arteries

A Infections and infestations

1 Meningovascular syphilis
2 Septic embolism
3 Arteritis secondary to pyogenic and tuberculous meningitis
4 Rare types (i e typhus schistosomiasis mansoni malaria(?) trichinosis(?) etc)

B Diseases of undetermined cause

1 Lupus erythematosus
2 Polyarteritis nodosa (necrotizing and granulomatous forms)
3 Cranial (temporal) arteritis
4 Idiopathic granulomatous arteritis of aorta and its major branches

VI Hypertensive encephalopathy

A Malignant hypertension (essential chronic renal disease pheochromocytoma etc)
B Acute glomerulonephritis
C Eclampsia

GENERAL ASPECTS

The Cerebrovascular Stroke as a Clinical Phenomenon The clinical picture resulting from vascular disease is in most instances so distinctive that the diagnosis is more readily made than any other in the realm of neurology The cardinal feature is the *stroke* a term which connotes the sudden and dramatic development of a focal neurologic deficit In the severest form of a stroke the patient falls unconscious and inert with evidence of hemiplegia—an event so striking as to deserve its own separate designation viz apoplexy stroke shock or cerebrovascular accident In its mildest form it may consist of only a trivial neurologic disorder insufficient to disturb the customary activities of the patient or to demand medical attention

Undoubtedly the most characteristic feature is

the sequence of events which may be called the *temporal profile* of the stroke It is the suddenness of onset that especially stamps the disorder as vascular The speed of evolution though variable depending on the cause is rapid and the deficit may require only seconds minutes hours or at most a few days to develop When the stroke develops over a period of several days it usually progresses in a stepwise fashion i e in a series of sudden changes rather than smoothly A slow gradual downhill course over a period of days or weeks indicates that the process is probably not vascular in nature Later in the course of the illness if the attack is not fatal some degree of stabilization and then recovery occurs Not infrequently an extensive deficit reverses itself dramatically within a few hours or a day More often however the improvement is gradual taking place over weeks and months

It must not be supposed that every neurologic abnormality in patients with cerebrovascular disease can be related by the patient or his family to a stroke Often the exact date of onset of a given symptom cannot be remembered One has the impression that some of the vascular incidents especially in the hypertensive patient are so mild that they do not attract notice until their cumulative effects become manifest as a neurologic deficit of indeterminate date Furthermore patients with lesions in the right (nondominant) parietal region and anosognosia often cannot be depended upon to give any of the important details of their illness

The neurologic deficit in a stroke depends of course on the location of the infarct or hemorrhage in the brain and the size of the lesion Hemiplegia is the classical sign of vascular disease and occurs chiefly with massive lesions of either cerebral hemisphere but also with lesions of the brain stem In the most serious cases of hemorrhage the patient literally falls in his tracks paralyzed on one side and soon passes into deep coma and dies within a few hours In other cases more commonly in infarction the patient although hemiplegic remains alert and from the beginning it is obvious that he will survive his illness whether or not neurologic recovery occurs A stroke however may give rise to many manifestations other than a hemiplegia e g numbness sensory deficit dysphasia blindness double vision dizziness dysarthria etc In the following paragraphs these manifestations will be emphasized equally with hemiplegia

To summarize briefly it might be said that the stroke is the common denominator of all cerebrovascular disease and is recognized chiefly by its temporal profile and characteristic focal neurologic deficit

In practice however the diagnosis of cerebrovascular disease is established by the entire constellation of clinical features Often the patient is elderly and arterial hypertension is present There may be evidence of vascular disease at other sites e g heart lower limbs and aorta or the patient may have diabetes mellitus and thereby be predisposed to atherosclerosis A source of emboli may be present (auricular fibrillation myocardial infarction subacute bacterial endocarditis etc) Many strokes are preceded by transient warning episodes of weakness numbness dizziness etc and these attacks if they are nonconvulsive in nature should always suggest thrombotic cerebrovascular disease The neurologic signs may occur in certain combinations having a neurovascular relationship i e they may depend on structures which lie within a given vascular territory as in the lateral medullary syndrome and thus suggest occlusive vascular disease And last but not least the presence of blood in the cerebrospinal fluid signifies that the process is vascular and diagnostic deductions can proceed from that vantage point

CEREBRAL THROMBOSIS WITH ATHEROSCLEROSIS

Atherosclerosis in the arteries of the brain is similar to that elsewhere in the body The atheromatous plaques tend to form at branchings and curves The severity of the process runs parallel to that of other arteries aorta lower limbs and heart Thrombosis is most likely to occur where the plaque narrows the lumen to the greatest degree The commonest sites of thrombosis are the internal carotid artery at the carotid sinus in the neck and at the siphon intracranially at the main bifurcation of the middle cerebral artery in the region of the vertebral basilar junction in the posterior cerebral artery as it winds round the cerebral peduncle and in the anterior cerebral artery as it curves upward over the corpus callosum Hypertension aggravates the process and leads to deposition of atheromatous material in smaller vessels (1 mm and less) and thrombosis will then occur in the penetrating branches of the middle posterior cerebral and basilar arteries producing small infarcts called *lacunes* in the deeper parts of the basal ganglions and brain stem The details of the process by which thrombosis becomes superimposed on atherosclerosis are poorly understood It is a fairly reliable rule that when the systemic blood pressure is maintained atherosclerosis by itself is asymptomatic to lead to symptoms it must be combined with thrombosis unless hypotension occurs

The effect of atherosclerotic thrombosis on the brain is not easy to predict accurately and this is also true of embolic occlusion If the obstruction lies proximal to the circle of Willis collateral flow via the circle may be and often is adequate to

2 Cerebral venous thrombosis
3 Systemic hypotension
4 Complications of arteriography
5 Arteritis (see V)
6 Hematologic disease (polycythemia sickle cell disease thrombotic thrombopenia etc)
7 Dissecting aortic aneurysm
8 Trauma to carotid
9 Hypoxia
10 Radioactive or x ray radiation
11 With tentorial foramen magnum and subfalcial herniations
12 Miscellaneous rare types (e g migraine)

D Cerebral infarction of undetermined cause

II Transient cerebral ischemia without infarction
A Recurrent cerebral ischemic attacks (previously called vasospasm usually associated with atherosclerosis and thrombosis)
B Systemic hypotension (i e simple faint acute blood loss myocardial infarction Stokes Adams syndrome traumatic and surgical shock sensitive carotid sinus severe postural hypotension)
1 With focal neurologic deficit
2 With syncope
C Migraine

III Intracranial hemorrhage (including intracerebral subarachnoid and ventricular rarely subdural)
A Hypertensive intracerebral hemorrhage
B Ruptured saccular aneurysm (if unruptured see IVA)
C Angioma (if unruptured see IV*B*)
D Trauma
E Hemorrhagic disorders (leukemia aplastic anemia thrombopenic purpura liver disease complication of anticoagulant therapy hyperfibrinolysis etc)
F Hemorrhage of undetermined cause (normal blood pressure and no angioma)
G Hemorrhage into primary and secondary brain tumors
H Septic embolism mycotic aneurysm
I With hemorrhagic infarction arterial or venous (see under I and VII)
J Secondary brain stem hemorrhage (temporal lobe herniation)
K Hypertensive encephalopathy
L Idiopathic brain purpura
M With inflammatory disease of arteries and veins (see under V VII)
N Miscellaneous rare types

IV Vascular malformations and developmental abnormalities
A Aneurysm—saccular fusiform globular diffuse (if ruptured see III*B*)
B Angioma [including familial telangiectasia trigeminal encephaloangiomatosis of Sturge Weber Dimitri and retinal pontine hemangiomas (if ruptured see IIIC)]
C Absence hypoplasia or other abnormality of vessels (including variations in pattern of circle of Willis)

V Inflammatory diseases of arteries
A Infections and infestations
1 Meningovascular syphilis
2 Septic embolism
3 Arteritis secondary to pyogenic and tuberculous meningitis
4 Rare types (i e typhus schistosomiasis mansoni malaria(?) trichinosis(?) etc)
B Diseases of undetermined cause
1 Lupus erythematosus
2 Polyarteritis nodosa (necrotizing and granulomatous forms)
3 Cranial (temporal) arteritis
4 Idiopathic granulomatous arteritis of aorta and its major branches

VI Hypertensive encephalopathy
A Malignant hypertension (essential chronic renal disease pheochromocytoma etc)
B Acute glomerulonephritis
C Eclampsia

VII Dural sinus and cerebral vein thrombosis
A Secondary to infection of ear paranasal sinus face or other cranial structures
B With meningitis and subdural empyema
C Debilitating states (marantic)
D Post partum
E Postoperative
F Hematologic disease (polycythemia sickle cell disease)
G Cardiac failure and congestive heart disease
H Miscellaneous rare types
I Of undetermined cause

VIII Strokes of undetermined origin

IX Vascular diseases without changes in the brain

GENERAL ASPECTS

The Cerebrovascular Stroke as a Clinical Phenomenon The clinical picture resulting from vascular disease is in most instances so distinctive that the diagnosis is more readily made than any other in the realm of neurology The cardinal feature is the stroke a term which connotes the sudden and dramatic development of a focal neurologic deficit In the severest form of a stroke the patient falls unconscious and inert with evidence of hemiplegia —an event so striking as to deserve its own separate designation viz apoplexy stroke shock or cerebrovascular accident In its mildest form it may consist of only a trivial neurologic disorder insufficient to disturb the customary activities of the patient or to demand medical attention

Undoubtedly the most characteristic feature is

common Often there is evidence of vascular disease elsewhere e g angina pectoris electrocardiographic abnormality myocardial infarction absence of peripheral pulses in the lower limbs or intermittent claudication The retinal arteries may show uniform or focal narrowing increase and irregularity of the light reflex or displacement of the veins but these alterations cannot be correlated with cerebral atherosclerosis and thus fundoscopic examination is at present of little or no help in assessing the state of the intracranial arteries

The *specific neurologic abnormality* depends of course on the location and size of the infarct or the focus of ischemia The territory of any vessel may be affected large or small deep or superficial The carotid and basilar systems are approximately equally affected In involvement of the carotid system unilateral signs predominate hemiplegia hemihypesthesia hemianopia aphasia and agnosia In the basilar system hemiplegia may also be found but more commonly involvement here results in the occurrence of *bilateral* signs motor and/or sensory in combination with a disturbance of cranial nerves cerebellum or other structures localized in or related to the brain stem In order for carotid occlusion to cause bilateral signs the vessels to both hemispheres would have to be affected at the same time and this is uncommon (bilateral carotid occlusion) Therefore in identifying vascular syndromes it is important to determine if the signs and symptoms indicate unilateral or bilateral lesions

In order to understand the particular groupings of neurologic symptoms and signs the student must be familiar with certain points of neurovascular anatomy which will now be presented The clinical picture associated with occlusion of each of the cerebral and cerebellar arteries will then be understandable It must be remembered that because of the differences in collateral blood flow speed of occlusion etc the effect of occlusion at any one site is highly variable and therefore partial syndromes and minor modifications are extremely common indeed they are in the majority The following descriptions apply to infarction and ischemia due to thrombosis or embolism While hemorrhage in the same sites may give rise to many of the same effects nevertheless the total clinical picture is apt to differ because in its deep extension the hemorrhage may involve the territory of more than one vessel Also it displaces tissues and causes an increase in intracranial pressure

Vascular Ischemic Syndromes *Middle Cerebral Artery* The middle cerebral artery through its cortical branches supplies the lateral surface of the hemisphere except for the frontal pole a strip along the superomedial border supplied by the anterior cerebral and the lowermost temporal convolution, which is supplied by the posterior cerebral artery

Table 131 DEVELOPMENT OF THE CLINICAL PICTURE IN 125 CASES OF CEREBRAL THROMBOSIS

Clinical development	No of cases	Percentage
1 Stroke developing as a single event	21	17
a Abrupt (hours) with or without fluctuations	*14*	
b Slow gradual (several days) with or without minor fluctuations	*7*	
2 Stepwise development of a stroke with or without transient ischemic attacks	23	18
3 Transient ischemic attacks progressing to a persistent neurologic deficit major or minor	53	42
4 Development of a limited stroke followed by transient ischemic attacks	11	9
5 Transient ischemic attacks only	17	14

Its area includes all the lateral and inferior part of the frontal lobe cortex and white matter the motor cortex (areas 4 and 6 the centers for contraversive eye movements and in the dominant hemisphere the motor speech area of Broca) the lateral and inferior part of the parietal lobe cortex and white matter (sensory cortex angular and supramarginal convolutions) the lateral and superior parts of the temporal lobe and the insula The penetrating branches of the middle cerebral artery supply the putamen outer globus pallidus the posterior limb of the internal capsule above the plane of the upper border of the globus pallidus the adjacent part of the corona radiata the body of the caudate nucleus and the superior portion of the head of the caudate nucleus (Fig 192)

The middle cerebral artery is the most frequently affected artery in embolic and thrombotic cerebrovascular disease It may be occluded in its stem [3] blocking the mouths of the penetrating vessels as well as the flow to the superficial (cortical) vessels or its major branches can be involved individually Foix and Levy recognized eight territorial syndromes (1) total middle cerebral infarction (deep and superficial) (2) major deep middle cerebral

[3] The term *stem* refers to the section of artery lying between the origin of the middle cerebral and the first major branching The stem of the anterior cerebral artery lies between its origin and the junction with the anterior communicating artery The stem of the posterior cerebral stretches from its origin to the posterior communicating artery The stem of the internal carotid artery extends from the region of the clinoid process to the bifurcation into the middle and anterior cerebral arteries

prevent infarction If the occlusion is distal to the circle of Willis i e in the stem of one of the cerebral or cerebellar arteries a series of subarachnoid interarterial anastomoses which join many of the branches of the major cerebral arteries end to end may carry sufficient blood into the compromised territory to prevent or lessen the ischemic damage (Fig 195) There is a capillary anastomotic system between adjacent brain arteries that appears always to be the source of some collateral supply probably inconsequential The collateral inflow is occasionally so great that a major trunk can be entirely occluded without visible damage to the parenchyma In other cases occlusion may lead to softening throughout a vast area which extends to the outermost boundaries of the territory nourished by the affected vessel In between these two extremes there are countless variations in the size shape and completeness of an infarct depending on factors such as the availability of collateral flow the speed of occlusion (time for compensation) and the level of the systemic blood pressure For convenience these factors (the most important of which is the anastomotic circulation) may be called the *ischemia modifying factors* These factors and possibly others such as hypoxia increased cerebral metabolism and altered physical state of the blood may also at times operate adversely to produce ischemia in the territory of partially occluded vessels

The Clinical Picture In general the evolution of the total clinical picture in cerebral thrombosis is much more variable than in embolism and hemorrhage In approximately 80 per cent of cases the main part of the stroke (paralysis or other deficit) is preceded by minor signs or by one or more transient warning ischemic attacks which in a sense herald the oncoming vascular catastrophe *A history of such prodromal episodes is of paramount importance in establishing the diagnosis of cerebral thrombosis* Such episodes do not precede intracerebral hemorrhage and are uncommon with embolism Transient warning attacks may consist of paralysis of a part of the body a unilateral numbness dizziness diplopia impaired vision in one or both eyes dark vision dysarthria headache head pain deafness etc depending on the part of the brain involved They last from a few seconds to an hour or so and the final stroke may be preceded by hundreds of them or by only a single one The stroke may come within a day of the first one or may be delayed for weeks or even months When these minor ischemic attacks are not part of the picture one must depend on other factors in identifying the cerebrovascular process as one of cerebral thrombosis

The main part of the thrombotic stroke whether or not it is preceded by warning attacks develops in one of several ways There may be but a single attack the whole illness developing at once The patient may awaken in the morning with a full blown paralysis or deficit of some other kind or have it come on shortly after arising perhaps while eating breakfast Another pattern is for the stroke once it commences to have a stuttering progression in the next few hours Or a partial stroke may develop and after the patient has improved for several hours a full paralysis may develop Again after one or more fleeting episodes there may be a longer lasting attack succeeded in a day or two by the occurrence of a complete and permanent paralysis The affection may involve several parts of the body simultaneously or as not infrequently happens one part e g a limb or one side of the face is first paralyzed and the other parts become involved serially in steplike fashion until the stroke is fully developed This may take several days or weeks during which time there may be *transient* episodes of improvement or worsening All these various modes of development bespeak cerebral thrombosis It might be added that in transitory attacks and the abrupt episodes of progression which are such common features the temporal profile of the stroke syndrome is duplicated in miniature In thrombotic strokes either the onset or progression of the stroke is particularly common during sleep or shortly after arising (60 per cent of cases) Occasionally a thrombotic stroke comes on in what appears to be a slow gradual fashion but in most of these cases careful inquiry will reveal an uneven or saltatory progression and actually there are only a few patients in whom it can be said that the evolution of the thrombotic stroke was truly gradual over a period of several days Table 131 shows the way in which the clinical picture developed in 125 cases of cerebral thrombosis diagnosed clinically for the most part

Headache is commonly associated with cerebral thrombosis generally being on one side in the front part of the head in occlusion of the carotid system and at the back of the head or in the forehead in basilar disease Many exceptions are to be noted however in which there is no headache at any time either before or during the thrombotic stroke The headache is usually not so violent as in cases of intracranial hemorrhage Its cause is unknown Presumably it is related in some way to the disease process within the vessel since it may antedate the other symptoms of the stroke Stiffness of the neck rarely occurs with cerebral infarction and when it does is related to temporal lobe or cerebellar herniation

The patient although usually elderly is not invariably so and persons in the fourth decade or even younger may be stricken Hypertension an important aggravating factor in atherosclerosis is more often present than not Diabetes is not un

agraphia alexia (visual verbal agnosia)] acalculia (inability to calculate) finger agnosia (inability to recognize fingers and parts of the body) and right left disorientation (inability to tell right from left) The last four of these symptoms comprise the well known *Gerstmann s syndrome* (see Chap 27) Ideational apraxia is another common finding This is an inability to carry out a purposeful act, presumably because of the faulty function of that part of the brain which conceives and initiates a desired performance with the result that the motor apparatus is not guided through the proper series of movements In partial lesions these symptoms may occur singly or in various combinations When the

Fig 193 Diagram of the lateral aspect of the cerebral hemisphere showing the branches and distribution of the middle cerebral artery and the principal regions of cerebral localization Below is a list of the clinical manifestations produced by infarction in the superficial territory of the middle cerebral artery and the corresponding regions of cerebral damage In each case the signs and symptoms are separated from the anatomic area by a colon ( )

Paralysis of the contralateral face arm and leg Somatic motor area and the fibers descending from above to enter the corona radiata

Sensory impairment over the contralateral face arm and leg (pinprick touch vibration position two point discrimination stereognosis tactile localization barognosis cutaneographia) Somatic sensory area

Motor aphasia Motor speech area of the dominant hemi phere

Sensory aphasia [word deafness anomia jargon speech sensory agraphia amusia acalculia alexia finger agnosia right left confusion (the last 4 comprise the Gerstmann syndrome)] Sensory speech area of the dominant hemisphere

Ideational apraxia Sensory speech area (parietal portion)

Apractognosia of the minor hemisphere (anosognosia hemiasomatognosia unilateral neglect dressing apraxia spatial agnosia l ss of topographic memory distortion of visual coordinates con structional apraxia etc) Nondominant *supersensory zone* (area corresponding to speech area in opposite hemisphere)

Homonymous hemian pia (often homonymous inferior quadrantanopia) Optic radiation deep to second tem poral c nvolution

Paraly is of conjugate gaze to the oppos te de Frontal contraversive field or fibers projecting therefrom

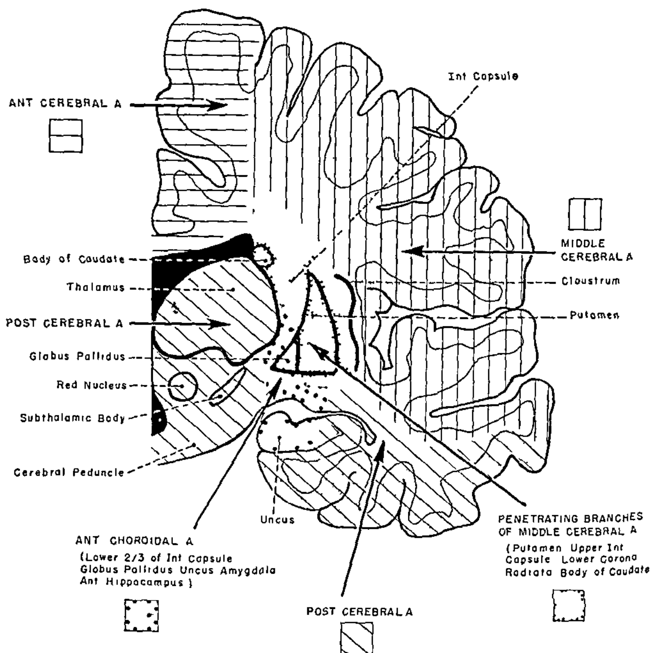

FIG 192 Diagram of a cross section of cerebral hemisphere to show the deep and superficial territories of the major cerebral vessels

infarction (3) partial deep middle cerebral infarction (4) major superficial middle cerebral infarction (5) major posterior middle cerebral infarction (6) partial posterior middle cerebral infarction (7) partial anterior middle cerebral infarction (8) multiple infarction unilateral and bilateral

The classical picture of total superficial and deep middle cerebral infarction is a contralateral hemiplegia hemianesthesia and homonymous hemianopia (Fig 193) If the dominant hemisphere is involved global or total sensorimotor aphasia also is present If the nondominant hemisphere is affected speech is spared but apractognosia of the minor hemisphere is added to the clinical syndrome (see below)

In the middle cerebral territory the motor and sensory cortical zones are spread out over a large area and hence an infarct of restricted size can produce paralysis of the face alone or of only one limb or even part of a limb This restricted deficit is referred to as a *monoplegia* or *monoparesis* (facial brachial crural)

An infarct which lies posteriorly in the superficial middle cerebral territory of the dominant hemisphere may cause hemianopia sensory aphasia [auditory verbal agnosia jargon speech anomia

held responsible for a partial motor speech deficit

Anterior Choroidal Artery A few incomplete clinicopathologic studies have been the basis of present knowledge of the syndrome of the anterior choroidal artery It is said to consist of contralateral hemiplegia hemianesthesia (hypesthesia) and homonymous hemianopia all due to involvement of the posterior limb of the internal capsule and the white matter posterolateral to it through which the first part of the geniculocalcarine fibers pass In the reported cases however the clinical syndrome usually fell far short of what was expected on anatomic grounds Furthermore the practice of surgically occluding the anterior choroidal artery in the treatment of parkinsonism has shown that hemiplegia hemianesthesia and hemianopia rarely occur and in the pathologically studied cases the lesions have been most capricious and indeed in some no lesion at all has been found Because of the present uncertainty surrounding the syndrome no further discussion of it will be given here

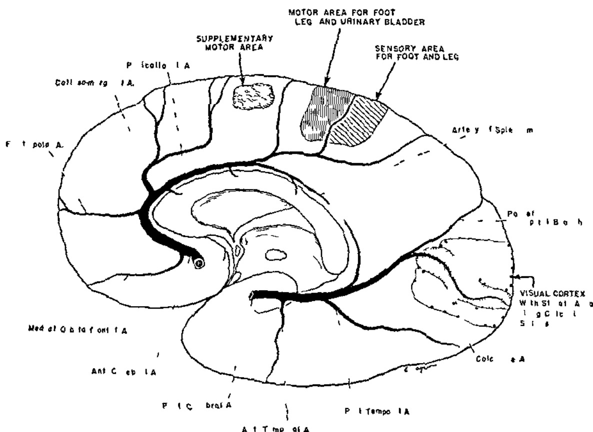

FIG 194 Diagram of the medial aspect of the cerebral hemisphere to show the branches and distribution of the anterior cerebral artery and the principal regions of cerebral localization Below is a list of the clinical manifestations produced by infarction in the territory of the anterior cerebral artery and the corresponding regions of cerebral damage In each case signs and symptoms are separated from the anatomic area by a colon ( )

Paralysis of opposite foot and leg Motor leg area
Lesser degree of paresis of opposite arm Involvement of arm area of cortex or fibers descending to corona radiata therefrom
Cortical sensory loss over toes foot and leg Sensory area for foot and leg
Urinary incontinence Sensorimotor area in paracentral lobule
Motor apraxia of left limb Posterior superior frontal gyri and/or corpus callosum interrupting fibers coming from dominant hemisphere
Grasp reflex sucking reflex and counterholding on the opposite side of the body Medial surface of posterior frontal lobe supplementary motor area(?)
Apraxia of gait (frontal ataxia) Premotor area in superior frontal gyrus
Loss of memory mental impairment Localization not known
Akinetic mutism Bilateral frontal cingulate lesions(?) (Note that aphasia and hemianopia do not occur)

nondominant hemisphere is involved posteriorly apractognosia of the minor hemisphere (a combination of apraxias and agnosias) may dominate the picture or be the only finding This includes anosognosia (unawareness of the illness or disability) left asomatognosia (unawareness of the left side) constructional apraxia (inability to construct a simple object from its parts) loss of topographic memory (inability to revisualize spatial relations e g the floor plan of a house etc) dressing apraxia (inability to dress) etc

If the infarct lies centrally in the motor sensory strip hemiplegia with sensory change will be the chief finding and if situated further anteriorly paralysis often of the monoplegic form with little or no sensory deficit will predominate On the dominant side motor aphasia and agraphia will be present (see Chap 25) On the nondominant side motor impersistence (inability to maintain eyes closed or tongue out or to fix gaze etc) may be noted Deviation of the eyes to the side of the lesion (i e paralysis of conjugate lateral gaze to the opposite side) is extremely common with acute lesions of the anterior part of the middle cerebral territory

When the deep territory of the middle cerebral artery is involved i e the upper part of the posterior limb of the internal capsule the adjacent part of the corona radiata the putamen and the outer part of globus pallidus a total hemiplegia usually results face arm and leg being affected together rather than in monoplegic form This is because the motor fibers lie closely packed in the capsule and therefore destruction is less likely to single out the fibers to only one limb than it is in the cortex where the motor area extends over a wide territory The aphasic disorder if any which results from these deep lesions has not been sufficiently studied

Damage to the basal ganglions (putamen caudate) produces no specific clinical effects which have so far been recognized A hemianopia does not occur as a rule in lesions in the territory of the penetrating arteries since the optic radiation lies at a more inferior level

Hypertension combined with atherosclerosis results in thrombotic occlusion of individual penetrating branches running to the internal capsule and putamen and the resultant small infarctions 2 to 8 mm in extent are called *lacunes* When they involve the internal capsule a mild hemiplegia results recovery from which is often nearly complete Multiple *lacunes* involving the corticospinal and corticobulbar motor tracts cause the clinical picture of pseudobulbar palsy (more appropriately called *bipyramidal palsy*) featuring bilateral upper motor neurone signs i e spasticity increased tendon reflexes Babinski sign dysarthria and dysphagia Spasms of excessive crying or laughing marche a petit pas and mental impairment are also part of the picture *Lacunes* are sometimes said to be the basis of so called arteriosclerotic parkinsonism but it is doubtful if such an entity exists

Anterior Cerebral Artery The anterior cerebral artery through its cortical branches supplies the anterior four fifths of the medial surface of the cerebral hemisphere and also the medial part of the orbital surface of the frontal lobe the frontal pole a strip of the lateral surface along the superomedial border and the anterior seven eighths of the corpus callosum The deep branches which arise near the circle of Willis run chiefly to the anterior limb of the internal capsule and inferior part of the head of the caudate nucleus (see Fig 194)

Well studied cases of infarction of the territory of the anterior cerebral artery are not common and the syndrome of this artery has not been clearly determined as yet Again the clinical picture will depend on the size and location of the infarct which in turn depend on the site of the occlusion the pattern of the circle of Willis and the other ischemia modifying factors Occlusion of the stem of the anterior cerebral artery proximal to the anterior communicating artery is usually well tolerated since collateral flow will cross over from its mate of the opposite side The maximal disturbance occurs when both anterior cerebral arteries happen to arise from one anterior cerebral stem occlusion of the stem then results in a devastating infarction of the anterior cerebral territory of both hemispheres This may include bilateral pyramidal signs with paraplegia and profound mental symptoms The typical syndrome resulting from occlusion of one anterior cerebral artery distal to the circle of Willis includes paralysis and a cortical sensory deficit of the opposite lower limb (paracentral sensorimotor area) and possibly involvement of the opposite arm (fibers descending from the arm area through the central white matter to the internal capsule) mental changes such as forgetfulness akinetic mutism (lack of impulse and animation) motor apraxia (a localized inability to use a limb or a part to carry out a simple coordinated act) of the nondominant upper extremity grasping and sucking reflexes a special type of resistance to passive movement of the limbs (counterholding or *gegenhalten*) and incontinence of bowel and bladder The degree of impairment of sensory and motor function is variable Occlusion of individual branches of the anterior cerebral artery causes only a part of the total syndrome Hemianopia does not occur in anterior cerebral lesions nor has an aphasic difficulty been reported except in rare instances where a softening in the central white matter supplied by the penetrating or deep branches has been

The interpeduncular branches arising near its origin penetrate the brain stem to supply the red nucleus subthalamic nucleus of Luys substantia nigra the most medial part of the cerebral peduncle the oculomotor nucleus the reticular substance of the midbrain decussation of the superior cerebellar peduncles rubrothalamic tract medial longitudinal fasciculus and the medial lemniscus The thalamo perforating branches also arise here and pass to the inferior mesial and anterior parts of the thalamus Branches arising serially along the parent vessel as it encircles the midbrain supply the cerebral peduncle lateral part of the medial lemniscus corpora quadrigemina pineal gland lateral geniculate bodies choroid plexus and hippocampus The thalamogeniculate branches supply the pulvinar

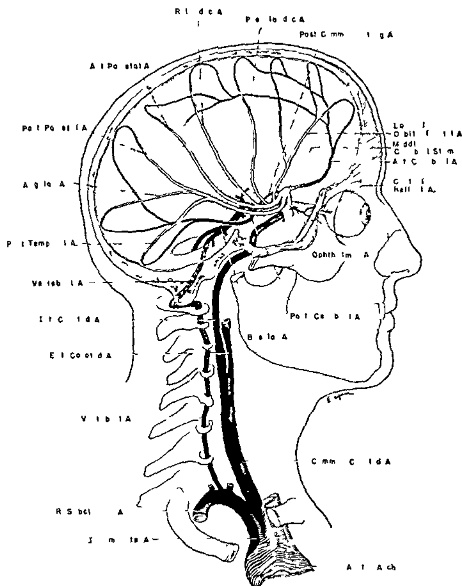

Fig 195 Drawing to illustrate the arrangement of the major arteries carrying blood from the heart to the brain (only the right side is shown) The posterior communicating artery connects the internal carotid and the posterior cerebral arteries forming an important anastomosis between the carotid and basilar systems Further distally the subarachnoid interarterial anastomoses which link the middle cerebral with the anterior and posterior cerebral arteries are shown The ophthalmic and central retinal arteries have been included *to remind* the student that observations and measurements of the retinal circulation provide information concerning the carotid circulation

Internal Carotid Artery The clinical picture of occlusion of the internal carotid artery is very variable Not infrequently occlusion is completely asymptomatic while in other cases it produces a devastating massive infarction which leads to death in a few days Between these two extremes lies every shade of variation As a rule the infarct involves the middle cerebral territory but when the anterior communicating artery is very small the ipsilateral anterior cerebral territory may be affected too in which case the anterior part of the hemisphere (the frontal lobe) bears the brunt of the insult while the region posterior to the rolandic fissure tends to be spared When both anterior cerebral arteries arise from a common stem on one side infarction may involve the anterior cerebral territory bilaterally Likewise the posterior cerebral artery may be supplied from the internal carotid rather than from the basilar artery in which case its territory too may be softened and thus the entire hemisphere and even part of the other may be involved Not infrequently the territory of the anterior choroidal artery is infarcted too When one carotid has been asymptomatically occluded at a previous time occlusion of the other can result in bilateral hemispheric infarction

In symptomatic occlusion of the internal carotid artery the picture usually resembles that of middle cerebral occlusion with a contralateral hemiplegia and hemihypesthesia and aphasia when the dominant hemisphere is involved The relative sparing of the posterior part of the hemisphere is reflected in a low incidence of homonymous hemianopia When the anterior cerebral territory is also involved the clinical picture will include some or all of the features already mentioned under anterior cerebral territory Patients with infarction in the combined territories of the middle and anterior cerebral arteries are much less responsive than those with lesions in only one territory and often they are in a state of light coma No special signs attributable to anterior choroidal involvement have so far been identified

In addition to supplying the brain the internal carotid artery is also the source of blood supply for the optic nerve and retina via the ophthalmic artery (Fig 195) Thus in some instances of carotid occlusion the picture of central retinal artery occlusion is found contralateral to the hemiplegia a puzzling picture until the underlying vascular arrangement is recalled Transient monocular blindness may have occurred intermittently as a warning symptom prior to the onset of the stroke

Whereas most cerebral vessels are inaccessible within the skull and topical diagnosis is made only by inference in carotid occlusion more direct diagnostic tests are available Pulsation may be lacking in the internal common or external carotid arteries when they are palpated in the neck or when the internal carotid artery is palpated in the pharynx Also pressure in the central retinal artery is often reduced on the side of the carotid occlusion and a pressure difference in the two eyes on careful ophthalmodynamometry will point strongly to carotid occlusion Another test consists of compressing the patent opposite carotid artery in the neck precipitating unconsciousness or seizures but such a maneuver cannot be recommended for routine use An additional sign of carotid occlusion is the presence on the opposite side of an intracranial murmur which may be heard by the patient or the examiner or both this murmur is presumably due to enhanced blood flow through the remaining patent vessel The bruit is heard best by placing the bell of the stethoscope over the eyeball but in some cases it is also heard over the temple or cheek When headache associated with cerebral thrombosis or embolism is unilateral and situated just above the eyebrow involvement of the middle cerebral or internal carotid artery is suggested

The common carotid arteries may be occluded at their origin particularly in "pulseless disease or the *aortic arch syndrome* The neurologic symptoms and signs of carotid occlusion just discussed may or may not be present depending on the adequacy of the circle of Willis and of the vertebral basilar system The following manifestations for the most part nonneurologic have been reported in the aortic arch syndrome absence of pulsation in carotid and radial arteries faintness on arising from the horizontal position recurrent loss of consciousness headache neck pain paresthesias of various parts of the body transient blindness (unilateral or bilateral) dimness of vision with exercise premature cataracts retinal atrophy and pigmentation atrophy of the iris leukomas peripapillary arteriovenous anastomoses optic atrophy claudication of the jaw muscles perforation of the nasal septum saddle nose deformity trophic ulceration of the face facial atrophy (unilateral or bilateral) indolent infections of the face abnormal facial pigmentation and loss of hair This condition was originally described in Japan particularly in young Japanese women who were found to be suffering from a granulomatous arteritis (Takayasu s disease see Chap 229) The majority of the authors cases of pulseless disease have been due to severe atherosclerosis

Vertebral basilar posterior cerebral System *Posterior Cerebral Artery* The terminal or cortical branches of this vessel supply the undersurface of the temporal and occipital lobes as well as the entire medial surface of the occipital lobe including the visual area (areas 17 18 and 19) Many important branches arise from the more proximal part of the artery between its origin at the bifurcation of the basilar artery and the cortical distribution

tion) tend to be associated with an inferior quadrantanopia More often the defect is hemianopic When only the central part of the visual field is affected there may be a hemianopic scotoma Scintillating phenomena i e flashes of light crude white or colored figures which suddenly appear in the affected part of the visual field are not uncommon The patient s awareness of the visual disturbance is variable He may be totally unaware of the defect which is discovered for the first time by the examiner or he may have vaguely appreciated that something was wrong with one eye In the acute stages with large temporooccipital lesions the opposite extreme may be encountered in that the patient reports that he is able to see only one half of objects or words or states that he is totally blind when he obviously is not When the lesion lies in the dominant hemisphere a dysphasic disturbance not yet clearly delineated may result The most prominent feature of it is alexia the patient reading very laboriously and having great difficulty in seeing letters but when given sufficient time comprehending what he reads The reading material is sometimes held at an angle and in rare instances the patient may read better when the lines are placed vertically The capacity for re visualization of spacial relationships (the ability to imagine the topography of home or town) may be lost and the ability to name persons may be impaired With large lesions of the dominant hemisphere temporary disorientation and memory loss occur possibly because of damage to the hippocampal and lingual gyri Color blindness total or in the half field is a prominent finding Visual object agnosia (inability to recognize objects) tactile agnosia or asymbolia metamorphopsia (objects appearing too small or too large or distorted) and simultanagnosia (inability to synthesize the elements of a scene into a whole) also occur

Bilateral lesions of the occipital lobes if extensive cause total blindness of the cortical type because of a bilateral homonymous hemianopia The pupillary reflexes are retained and fundoscopically the optic nerves are normal unlike blindness from retinal and optic nerve or tract disease Often the patient is unaware of the blindne s and may in fact deny it when questioned specifically And with bilateral lesions there is usually a loss of memory which varies from case to case More commonly the bilateral lesions are incomplete and the patient is left with a sector of visual field intact In small calcarine lesions there may be loss of central vision only (bilateral homonymous central scotomas) or on the other hand in larger calcarine lesions only central vision may be spared and vision is likened to looking through a narrow pipe

When occlusion of the posterior cerebral artery occurs more proximally (one might speak of anterior syndromes) the clinical picture will comprise signs of damage to thalamus cerebral peduncle midbrain and hypothalamus and in addition the manifestations just described (hemianopia etc) may or may not be present depending on the collateral inflow of blood Best known is the *thalamic syndrome* of Dejerine and Roussy which results from infarction of the region of the sensory nucleus in the posterolateral part of the thalamus (supplied by the thalamogeniculate vessel) The lesion may be so small as to be overlooked on pathologic examination The central feature is a sensory loss on the opposite side of the body usually affecting deep and superficial sensation (pain temperature touch proprioception) or rarely it may be of the dissociated type either pain and temperature or vibratory and position sense being affected while other sensory modalities are relatively spared It may take a monoplegic pattern Often there is an associated intractable agonizing pain in the affected parts of the body (thalamic pain) occurring spontaneously and augmented by all types of stimulation of the affected parts Hyperpathia and taste disorders are common In other patients spontaneous pain may be entirely missing In the motor sphere there may be a mild evanescent hemiparesis and in some patients the affected limbs show hemiballismus choreoathetosis incoordination intention tremor asynergy cramplike spasms and a postural abnormality of the hand (cf Chap 26) The mind is usually strikingly spared

Occlusion of the stem of the posterior cerebral artery may lead to a hemiplegia owing to infarction of the cerebral peduncle but this appears to be rather rare Occlusion of the thalamoperforate branches which originate from the most medial part of the posterior cerebral stem gives rise to several different syndromes depending on the branches involved (1) a superior syndrome in which the upper part of the red nucleus or rubrothalamic tract is involved producing on the opposite side of the body a gross ataxia (see Chap 26) (2) an inferior syndrome (Claude s syndrome) in which homolateral cerebellar signs and a third nerve palsy are combined (3) Weber s syndrome i e a third nerve palsy combined with a contralateral hemiplegia (see Chap 30) (4) *hemiballismus* which probably arises also from an occlusion of the branch of the posterior cerebral artery running to the subthalamic nucleus of Luys (5) paralysis of conjugate vertical gaze and at times of lateral gaze which results from damage to the tegmentum and tectum of the midbrain area (6) peduncular hallucinosis (visual hallucinations of brightly colored scenes and objects) have been observed in occlusion of the posterior cerebral artery but the site of the lesion has not been determined More often an intra

and the lateral nuclei of the thalamus (Fig 196)

Again the clinical picture resulting from occlusion will depend on the site of the obstruction the site and size of the infarct and the ischemia modifying factors Occlusion proximal to the posterior communicating artery may be tolerated if collateral flow via that vessel is adequate however the penetrating branches arising from the stem of the posterior cerebral artery may be occluded at their mouths Even distal to the posterior communicating artery occlusion may cause no damage if collateral flow via the subarachnoid interarterial anastomoses is sufficient

Classically occlusion of the cortical or superficial branches of the posterior cerebral artery gives rise to a contralateral homonymous hemianopia because of involvement of the primary visual area in the calcarine region Partial visual field defects are common and it is claimed that posterior cerebral lesions are likely to cause a superior homonymous quadrantanopia whereas middle cerebral lesions (involving the superior portion of the optic radia

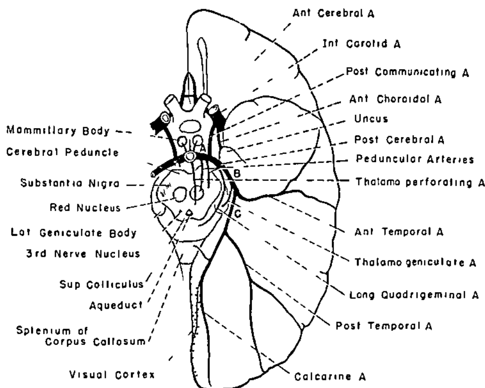

FIG 196 Diagram of the inferior aspect of the brain to show the branches and distribution of the posterior cerebral artery and the principal anatomic structures Below is a list of the clinical manifestations produced by infarction in the territory of the posterior cerebral artery and the corresponding regions of damage In each case the signs and symptoms are separated from the anatomic area by a colon ( )

Homonymous hemianopia (often upper quadrantic) Calcarine cortex or optic radiation nearby Hemiachromatopsia may be present

Bilateral homonymous hemianopia cortical blindness agnosia for blindness Bilateral calcarine cortex

Dyslexia visual agnosia associated tactile agnosia perseveration Calcarine and pericalcarine cortex in *dominant* hemisphere

Memory defect Hippocampal lesion bilaterally or on dominant side(?)

Thalamic syndrome—sensory loss (all modalities) spontaneous pain choreoathetosis intention tremor spasms of hand mild hemiparesis Posteroventral nucleus of thalamus in territory of thalamogeniculate artery (involvement of the latter results in hemiballismus) and also the subthalamic body

Thalamoperforate syndrome—cerebellar ataxia and third nerve palsy Third nerve and the red nucleus or rubrothalamic tract

Weber s syndrome—third nerve palsy and contralateral hemiplegia Third nerve and cerebral peduncle

Contralateral hemiplegia Cerebral peduncle

Paralysis of vertical eye movement Supranuclear fibers to third nerve(?)

Coma Damage to upper brain stem (midbrain thalamus)

Decerebrate attacks Damage to upper brain stem (especially motor tracts)

Static tremor has been omitted because of the uncertainty of its occurrence in the posterior cerebral syndrome

branch to the pyramid is occluded that part of the corticospinal tract may be infarcted unless collateral flow is adequate Of course each of these branches may become occluded somewhere along its course after leaving the vertebral artery and produce similar effects Rarely occlusion of the vertebral artery or one of its medial branches produces infarction of the pyramid in combination with involvement of the medial lemniscus and the emergent hypoglossal fibers [contralateral paralysis of *arm and leg (face spared) contralateral loss of* touch and vibration sense and ipsilateral wasting of the tongue] This is the medial medullary syndrome (see Fig 197D) Finally vertebral occlusion can lead to symptoms by blocking the posterior inferior cerebellar artery

The posterior inferior cerebellar artery supplies *the inferior portion of the lateral medullary region* the restiform body and the underbelly of the cerebellar hemisphere Occlusion may occur at its mouth in association with vertebral occlusion or anywhere along its course Some patients tolerate obstruction of this vessel with little or no ill effect in others an extensive cerebellar infarct results It should be pointed out that the various cerebellar arteries are connected to their neighbors by subarachnoid interarterial anastomoses in the same way as the main cerebral arteries and the potential *for collateral flow to a compromised territory is* excellent

The clinical picture resulting from occlusion of the posterior inferior cerebellar artery is highly variable Often no serious damage results At other times there may be dizziness homolateral cerebellar ataxia nystagmus and loss of equilibrium *due to involvement of the inferior surface of the*

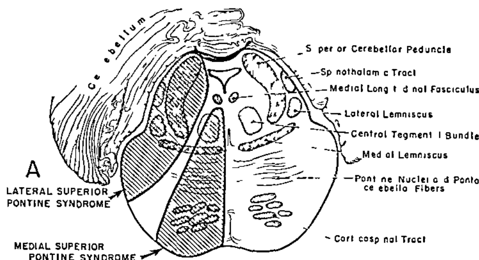

FIG 197A

1 MEDIAL SUPERIOR PONTINE SYNDROME (paramedian branches of upper basilar artery)

Signs and symptoms	*Structures involved*
On side of lesion	
Cerebellar ataxia (probably)	Pontine nuclei pontocerebellar fibers
Internuclear ophthalmoplegia	Medial longitudinal fasciculus
Myoclonic syndrome palate pharynx vocal cords respiratory apparatus face oculomotor apparatus	Central tegmental bundle? (localization *not agreed* upon)
On side opposite lesion	
Paralysis of face arm and leg	Corticobulbar and corticospinal tract

2 LATERAL SUPERIOR PONTINE SYNDROME (syndrome of superior cerebellar artery)

On side of lesion	
Ataxia of limbs and gait falling to side of lesion *nystagmus*	Middle and superior cerebellar peduncles superior sur*face of cerebellum* dentate nucleus
Miosis ptosis decreased sweating over face (Horner s syndrome)	Descending sympathetic fibers
Static tremor reported in one case	Dentate nucleus(?) superior cerebellar peduncle(?)
On side opposite lesion	
Impaired pain and thermal sense over limbs and half of body	Spinothalamic tract

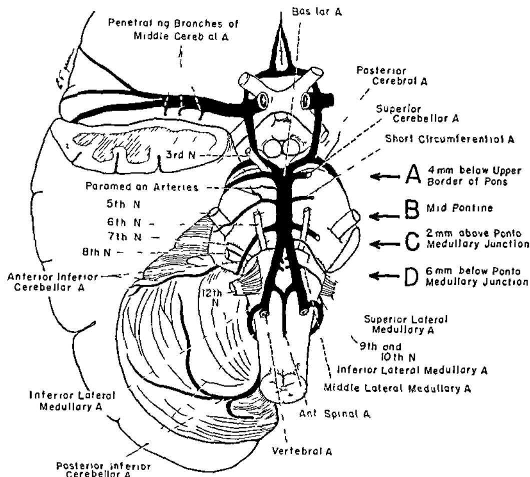

FIG 197 Diagram of the brain stem showing the principal vessels of the vertebral basilar system The letters and arrows on the right indicate the levels of the four cross sections A B C and D which follow Although typical vascular syndromes of the pons and medulla have been designated by sharply outlined shaded areas the student must appreciate that since satisfactory clinicopathologic studies are far from numerous the diagrams are not necessarily accurate nor do they always represent established fact The great frequency with which infarcts fail to produce a well recognized syndrome and the special tendency for syndromes to merge with one another must be emphasized

cerebral hemorrhage is responsible All these abnormalities are relatively uncommon in cerebrovascular disease Finally (7) extensive infarction of the upper midbrain results in deep coma and decerebrate rigidity (reflex extensor posture)

Vertebral Artery The vertebral arteries are the chief arteries of the medulla and each supplies the lower three fourths of the pyramid the medial lemniscus the lower half or more of the retroolivary region (the lateral medullary region) the restiform body and the posteroinferior part of the cerebellar hemisphere (see Fig 197) The relative size of the vertebral arteries varies a good deal and in approximately 10 per cent of cases one vessel is so small that the other can be considered the only artery of supply to the brain stem In this case depending on collateral inflow from the carotid system via the circle of Willis occlusion would be equivalent to occlusion of the total vertebral basilar system including the posterior cerebral arteries The posterior inferior cerebellar artery is usually a branch of the vertebral artery but not infrequently it has a common origin with the anterior inferior cerebellar artery from the basilar artery It is necessary to keep these anatomic variations in mind when visualizing the effects of vertebral artery occlusion

It would appear that when there are two good sized vertebral arteries occlusion on one side occurs not infrequently without any recognizable symptoms and signs or pathologic changes If the occlusion of the vertebral artery is so situated as to block the mouth of the middle artery of the lateral medulla the lateral medullary syndrome may be precipitated (see below) When the branch to the anterior spinal artery is blocked collateral influx from the spinal artery branch of the opposite side is usually sufficient to prevent infarction If the

separately e g superior cerebellar anterior inferior cerebellar superior lateral medullary artery etc It is convenient to separate the branches of the basilar artery into (1) paramedian seven to ten in number supplying a wedge of pons on either side of the midline (2) the short circumferential branches five to seven in number supplying the lateral two-thirds of the pons and the middle and superior cerebellar peduncles and (3) the long circumferential two in number to the cerebellar hemispheres (superior and anterior inferior cerebellar arteries) In occlusion of the basilar artery one might expect a vast array of clinical manifestations since the artery supplies a large number of structures (pontine nuclei corticospinal and corticobulbar tracts the cerebellum and middle and superior cerebellar peduncles medial and lateral lemnisci spinothalamic tracts medial longitudinal fasciculi

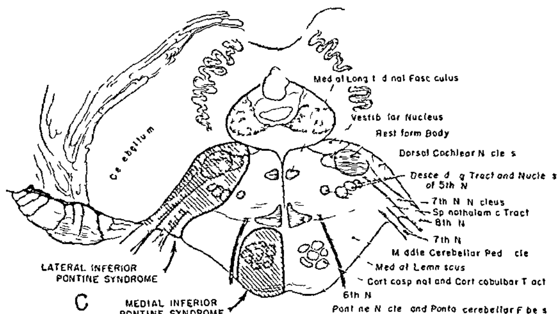

Fig 197C

5 MEDIAL INFERIOR PONTINE SYNDROME (occlusion of paramedian branch of basilar artery)

Signs and symptoms	*Structures involved*
On side of lesion	
Paralysis of conjugate gaze to side of lesion (preservation of convergence) nystagmus	Center for conjugate lateral gaze
Ataxia of limbs and gait	Pontine nuclei(?) pontocerebellar fibers(?)
Diplopia on lateral gaze	Abducens nerve
On side opposite lesion	
Paralysis of face arm leg	Corticobulbar and corticospinal tract in lower pons
Impaired tactile and proprioceptive sense over half of the body (of uncertain occurrence)	Medial lemniscus

6 LATERAL INFERIOR PONTINE SYNDROME (occlusion of anterior inferior cerebellar artery)

On side of lesion	
Deafness(?) tinnitus	Auditory nerve
Nystagmus vertigo nausea vomiting	Vestibular nerve or nucleus
Facial paralysis	Seventh nerve
Paralysis of conjugate gaze to side of lesion diplopia	Center for conjugate lateral gaze
Ataxia	Middle cerebellar peduncle
Impaired sensation over face (uncommon)	Descending tract and nucleus fifth nerve
On side opposite lesion	
Impaired pain and thermal sense over half of the body (may include the face)	Spinothalamic tract

7 TOTAL UNILATERAL INFERIOR PONTINE SYNDROME (occlusion of anterior inferior cerebellar artery) Combination of lateral and medial syndromes

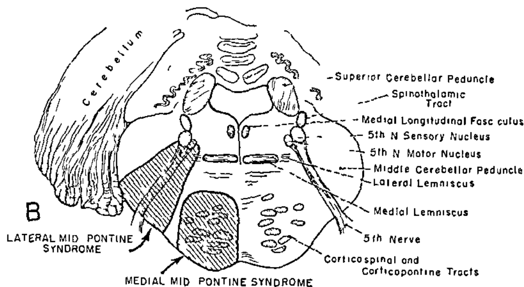

Fig 197B

3 MEDIAL MIDPONTINE SYNDROME (paramedian branch of midbasilar artery)

Signs and symptoms	*Structures involved*
On side of lesion	
Ataxia of limbs and gait (more prominent in bilateral involvement)	Pontine nuclei and pontocerebellar fibers
On side opposite lesion	
Paralysis of face arm and leg	Corticobulbar and corticospinal tract
Variable and transient impaired touch and proprioception (this has not been clearly established)	Medial lemniscus

4 LATERAL MIDPONTINE SYNDROME (short circumferential artery)

On side of lesion	
Ataxia of limbs	Middle cerebellar peduncle
Paralysis of muscles of mastication	Motor fibers or nucleus fifth nerve
Impaired sensation over side of face	Sensory fibers or nucleus fifth nerve

cerebellum and its connections with the brain stem Then again the *lateral medullary syndrome* may be evoked through blockage of flow along the inferior artery of the lateral medulla While occlusion of the posterior inferior cerebellar artery is usually stated to be the cause of the lateral medullary syndrome this appears to be true in only a minority of patients more careful studies have shown that in many instances occlusion of another vessel originating at a higher level a branch of either the vertebral or the lower basilar artery is responsible

The lateral medullary syndrome is produced by infarction of a small wedge of lateral medulla lying posterior to the inferior olivary nucleus (see Fig 197D) The classical syndrome consists of pain and numbness of the ipsilateral face (descending tract and nucleus of the trigeminal nerve) dizziness nausea vomiting nystagmus (vestibular nucleus or fibers) dysphagia ipsilateral palatal weakness hoarseness ipsilateral paralysis of vocal cord (nucleus ambiguus or issuing fibers) homolateral cerebellar ataxia of arm and leg disequilibrium with falling to the side of the lesion (cerebellum inferior cerebellar peduncle or olivocerebellar fibers) sensory loss (dissociated loss of pain and temperature sensation) on the opposite side of the body below the neck—sometimes the face is included (spinothalamic tract) ipsilateral Horner s syndrome (descending sympathetic tract) and hiccoughs Added to the basic picture there may be ipsilateral loss of taste (tractus solitarius) diplopia skew deviation or internuclear ophthalmoplegia (the medial longitudinal fasciculus vestibular connections or perhaps the sixth nerve) contralateral corticospinal signs (pyramid) loss of the knee jerks ipsilateral peripheral facial palsy paresthesias of the ipsilateral side hippus and trophic ulceration Many of these additional signs indicate extension of the lesion to a slightly higher level This syndrome one of the most striking in neurology is almost always due to vascular disease

Basilar Artery The basilar artery supplies not only the pons and upper cerebellum but in most cases both posterior cerebral territories too The trunk of the basilar artery itself may be occluded or any one of its many branches may be involved

vestibular and cochlear nuclei descending hypothalamospinal sympathetic fibers the upper medulla and cranial nerves III IV V VI VII VIII (the nuclei the segment within the brain stem and the peripheral nerve itself) see Fig 197]

Basilar occlusion may arise in several ways thrombosis may occur on an atherosclerotic plaque in the lowermost basilar artery near its origin both vertebral arteries may become occluded by atherosclerotic thrombosis closure of the second being equivalent to basilar obstruction atherosclerotic occlusion of a single vertebral (when there is only one of good size) is equivalent to basilar occlusion atherosclerotic thrombosis may involve only a branch rather than the trunk of the basilar artery *and this is probably the commonest cause of basilar* symptomatology finally *the obstruction* may be embolic the embolus usually lodging at the upper bifurcation of the basilar or in one or other posterior cerebral artery since *if it is small enough* to pass through the vertebral artery it should easily traverse the length of the basilar artery which is usually of greater diameter than either vertebral artery

In the complete basilar syndrome *examination* shows principally paralysis of all *four extremities* (usually *one side is more affected than the other*) and the bulbar musculature dysarthria dysphagia diplopia and sensory loss for pain *temperature* touch and vibration (motor paralysis *usually* predominates over sensory deficit) and perhaps impaired vision At the most advanced stage of the illness the patient is deeply comatose both voluntary and reflex eye movements are *absent* the pupils are fixed to light and may be dilated *respirations* are irregular the systemic blood pressure fluctuates and accesses of extensor rigidity may be evoked by pinch or other stimuli *Occasionally* with low pontine lesions the patient although totally paralyzed may be relatively alert but physically powerless to evince signs of the retained alertness except through signaling with eye *blinks* or eye movements (see p 311)

When the full basilar artery syndrome has developed it is usually not difficult to make the correct diagnosis The aim should be however to recognize basilar insufficiency before the stage of total deficit has been reached The early manifestations occur in many combinations and it would be difficult to list all the possibilities Most commonly the following will be encountered weakness or paralysis of one or both sides of the body occasionally a monoplegia only numbness and a corresponding sensory loss involving one entire side of the body or both sides of the body or one or both sides of the face or both hands or both legs or numbness of one side can be combined with paralysis of the other dysarthria speechlessness stuttering and dysphagia dizziness of a vestibular type either in attacks or upon change of posture often associated with nausea and vomiting diplopia due to a disturbance of the third or sixth nerves or resulting from faulty conjugate lateral gaze or internuclear ophthalmoplegia (see p 281) paralysis of conjugate lateral gaze to the side of the *lesion* (this is the reverse of hemispheric lesions where the patient is unable to turn his eyes toward the side of the paralysis) cerebellar ataxia involving the limbs of one or both sides *or affecting chiefly* the functions of walking and standing infranuclear palsy of the seventh nerve (facial paralysis) or the motor part of the fifth nerve (weakness of masseter muscle and deviation of the jaw to the side of the lesion) impaired vision blurred vision dark vision or scintillating scotomas loss of hearing either unilateral or bilateral and rarely tinnitus headache head pain or *peculiar head sensations (like a cord* being drawn tightly around the head) confusion impaired memory drowsiness (the patient may however be lucid) Rarer phenomena include bulbar myoclonus bilateral internuclear ophthalmoplegia facial fasciculations or twitchings simple auditory hallucinations and distortions of taste

It has already been pointed out that occlusion of individual basilar branches is very frequent In the case of the *superior cerebellar artery* the main signs are severe ipsilateral cerebellar ataxia (middle and/or superior cerebellar peduncles) instability of gait (involvement of the medial part of the superior surface of the cerebellum) nausea and vomiting slurred speech and loss of pain and temperature over the extremities body and face of the opposite side (spinothalamic tract) Partial deafness a static tremor of the ipsilateral upper extremity Horner s syndrome and bulbar myoclonus have also been reported In *occlusion of the anterior inferior cerebellar artery* it is well to remember that the extent of the infarct is variable The size of this artery and the territory it supplies vary inversely with that of the posterior inferior cerebellar artery The principal findings are ipsilateral cerebellar ataxia (middle cerebellar peduncle) Horner s syndrome ipsilateral deafness whirling dizziness facial palsy and sensory loss over the face Nausea vomiting tinnitus and nystagmus may be associated Pain and temperature sensation may be lost on the opposite side of the body If the occlusion is close to the origin of the artery the corticospinal fibers may also be involved producing a hemiplegia Other branches of the basilar artery may also be occluded individually occlusion of the artery to the retroolivary space will produce the lateral medullary syndrome occlusion of a paramedian branch will result in infarction of the corticospinal fibers on one side and of the adjacent pontine nuclei and pontocerebellar fibers

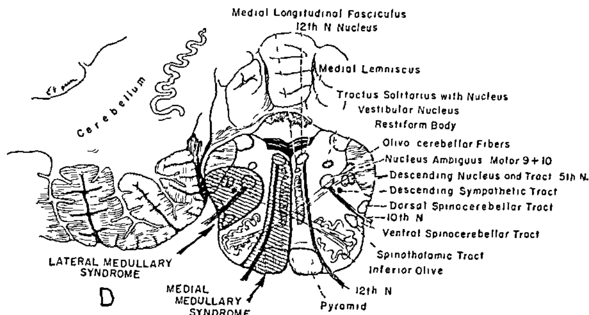

Fig 197D

8 MEDIAL MEDULLARY SYNDROME (occlusion of branch of vertebral or lower basilar artery)

Signs and symptoms	*Structures involved*
On side of lesion	
Paralysis with atrophy of half the tongue	Issuing twelfth nerve
On side opposite lesion	
Paralysis of arm and leg sparing face	Pyramidal tract
Impaired tactile and proprioceptive sense over half the body	Medial lemniscus

9 LATERAL MEDULLARY SYNDROME (occlusion of any of five vessels may be responsible)

On side of lesion	
Pain numbness impaired sensation over half the face	Descending tract and nucleus fifth nerve
Ataxia of limbs falling to side of lesion vertigo nausea vomiting nystagmus	Restiform body spinocerebellar tract vestibular fibers or nucleus
Miosis ptosis decreased sweating (Horner s syndrome)	Descending sympathetic tract
Dysphagia hoarseness paralysis of palate paralysis of vocal cord diminished gag reflex	Issuing fibers ninth and tenth nerves
Loss of taste	Nucleus and tractus solitarius
Hiccoughs also occur	
On side opposite lesion	
Impaired pain and thermal sense over half the body sometimes face	Spinothalamic tract

10 TOTAL UNILATERAL MEDULLARY SYNDROME (occlusion of vertebral artery) Combination of medial and lateral medullary syndromes

11 LATERAL PONTOMEDULLARY SYNDROME (occlusion of anterior inferior cerebellar artery or superior lateral medullary artery) Combination of lateral medullary and lateral inferior pontine syndromes

12 BASILAR ARTERY SYNDROME (the syndrome of the lone vertebral artery is equivalent)
[A combination of the various unilateral brain stem syndromes plus those arising in the posterior cerebral artery distribution Most often the clinical picture consists of bilateral long tract signs (sensory and motor) with cranial nerve and cerebellar disturbances]

Signs and symptoms	*Structures involved*
Paralysis or weakness of all extremities plus all bulbar musculature	Corticobulbar and corticospinal tracts bilaterally
Diplopia paralysis of conjugate gaze nystagmus	Ocular motor nerves apparatus for conjugate gaze medial longitudinal fasciculus vestibular apparatus
Blindness impaired vision various visual field defects	Visual cortex
Bilateral cerebellar ataxia	Cerebellar peduncles and the cerebellar hemispheres
Coma	Tegmentum of midbrain thalami

and the pulse although often not altered to an important extent in cerebral thrombosis may in basilar artery occlusion undergo a terminal rise the temperature rising to 104 to 106 F The blood pressure fluctuates but seldom falls to low levels

One cannot generalize about mental change stupor and coma in cerebral thrombosis for they are in large part related to both the site of the lesion and its massiveness (with secondary pressure effects on diencephalic and midbrain structures) Drowsiness apathy impairment of memory and mild degrees of confusion are extremely common in brain infarction due to cerebral thrombosis especially when the lesion is situated in a cerebral hemisphere However a patient with a complete hemiplegia right or left due to a hemispheral lesion may remain relatively alert and may be found propped up in bed reading or pretending to read the morning newspaper with small lesions of the motor system there may be no discernible intellectual change whatsoever When both the middle and anterior cerebral territories on one side are involved the patient s responses are usually minimal although he is generally awake or can be aroused Massive bilateral lesions of the cerebral hemispheres precipitate deep coma In bilateral lesions of the *basis pontis* almost total paralysis of the entire body musculature may be combined with a surprising degree of awareness but again when the tegmentum of the upper brain stem is softened deep coma results Spasmodic crying or laughing may be seen in unilateral lesions and is not always to be taken as a sign of bipyramidal palsy

When a massive hemispheral infarct has occurred there is always the possibility that severe cerebral swelling will follow in the next few days When this happens tentorial subfalcial or cerebellar herniation may occur and if the midbrain is seriously compressed deep coma dilated fixed pupils respiratory embarrassment and rising temperature presage a hopeless outcome In milder cases the patient passes through an extremely drowsy period and transient papilledema with a raised spinal fluid pressure may be encountered *Decerebrate posture* (reflex extensor rigidity) usually reflects irreversible damage to the midbrain or pons either by softening or as the result of Duret hemorrhages secondary to tentorial herniation and midbrain compression *Unilateral decerebrate posture* is seen not infrequently and does not carry with it the poor prognosis of the bilateral variety

Laboratory Findings Cerebral infarction does not alter renal function and any urinary abnormalities are to be attributed to concomitant renal disease Furthermore it does not occasion an important leukocytosis The cerebrospinal fluid pressure is usually normal in patients with cerebral thrombosis except with large infarcts associated with severe swelling of the damaged tissue Cerebral thrombosis virtually never causes blood in the spinal fluid the latter is usually "crystal clear" unless the infarct is especially congested when a very faint xanthochromia (1 to 2 on a scale of 10) may occur A slight increase in the leukocytes of the spinal fluid (3 to 8 polymorphonuclears) is common in the first few days of the illness Rarely and for unexplained reasons a brisk transient pleocytosis (400 to 2 000 polymorphonuclears per cubic millimeter) occurs on about the third day A persistent increase in the white blood cells of the cerebrospinal fluid suggests the presence of chronic meningitis (syphilis tuberculosis torula) granulomatous arteritis septic embolism cerebral thrombophlebitis or a nonvascular process The total protein may be normal but frequently it is raised to 50 to 80 mg per cent Rarely is it over 100 and when it is some other diagnosis should be seriously considered A Wassermann or some other specific test for syphilis is still routinely made in many clinics but can be dispensed with unless the rest of the clinical and laboratory picture points toward neurosyphilis A positive test in a bloody fluid is not valid since syphilitic reagin may have been carried into the fluid by the contaminating blood Skull x rays are not remarkable and the pineal gland will not be shifted unless severe cerebral swelling has occurred in which case the patient will usually be comatose or stuporous The electroencephalogram is still of limited value in indicating infarction or distinguishing it from hemorrhage and from nonvascular conditions In brain stem and capsular infarction the tracing is usually within normal limits Generally speaking in cerebral infarction the electrical activity is found to be of a slightly slower frequency and lower voltage than normal High voltage slow waves (3 to 5 per second) are evidence in favor of hemorrhage or tumor More thorough clinicopathologic electroencephalographic correlation studies are needed In distinguishing a vascular lesion from brain tumor serial electroencephalograms may be useful in that in the former the tracing tends to improve in the latter to worsen The pneumoencephalogram may be normal in the acute stages of arterial occlusion but later local ventricular dilatation may occur it indicates the site of tissue loss due to infarction This procedure is not recommended as a diagnostic laboratory test in patients with occlusive cerebrovascular disease because of the danger of precipitating a worsening in the neurologic syndrome possibly owing to the hypotensive state which so often attends the introduction of air Carotid arteriography a procedure widely used in many clinics to visualize the site of the vascular occlusion will demonstrate the blocked artery if it is in the carotid or in the proximal parts of the middle cerebral or

on the same side of the pons Smaller infarcts (lacunes) will result from occlusion of the smaller branches in patients with hypertension and athero sclerosis They may be responsible for or contribute to the syndrome of pseudobulbar palsy

One of the hallmarks of a brain stem lesion is the occurrence of bilateral pyramidal tract signs and/or bilateral sensory manifestations within the brain stem tracts descending to or ascending from each side of the body either cross mutually or run very close to one another as opposed to the cere bral hemispheres where the motor and sensory tracts subserving one side of the body are at a distance from those of the other side While it is correct to emphasize that bilaterality of a lesion strongly suggests brain stem involvement it must be pointed out with equal force that unilaterality of a lesion by no means precludes a brain stem site On the contrary in many instances of infarction within the basilar territory the lesion is strictly limited to one side bespeaking occlusion of a basilar branch rather than of the main trunk An other cardinal sign of involvement of the brain stem is evidence of a nuclear or infranuclear lesion of one or more cranial nerves especially if com bined with signs of long tract involvement

Additional manifestations which point unequivo cally to a brain stem lesion are whirling dizziness diplopia cerebellar ataxia Horner s syndrome and deafness Sensory disturbances may also be helpful in localization A dissociated sensory deficit over the face or one half the body (loss of pain and temperature sense and retention of vibration and position sense or vice versa) usually indicates a lesion within the brain stem a sensory loss over one side of the body involving all modalities indi cates a lesion at approximately the thalamic level or higher when position sense two point discrimi nation and tactile localization are affected relatively more than pain temperature and tactile sense a cortical lesion is suggested In the diagnosis of disease of the brain stem it is impossible from motor signs alone to distinguish a hemiplegia of pontine origin from one of cerebral origin except by the aid of coexisting phenomena As with cerebral lesions a flaccid paralysis gives way to spasticity in the following days weeks or months and there is no satisfactory explanation for the variability in this period of delay When both motor and the sensory manifestations are bilateral it is almost unequivocal evidence that the lesion lies infraten torially The several brain stem syndromes illustrate an important point—the cerebellar system spino thalamic tract trigeminal nucleus and the sympa thetic fibers can be involved at different levels Associated phenomena are necessary for the identi fication of the exact level of the lesion

A myriad of eponymic brain stem syndromes e g Weber Claude Benedikt Foville Raymond Cestan Millard Gubler etc already mentioned in pp 290 to 291 have been described with brain stem lesions However most of them relate to cases of tumor and other nonvascular diseases and only occasionally is one of these syndromes en countered in association with vascular disease The diagnosis of vascular disease in this region of the brain is not greatly facilitated by a knowledge of these classical syndromes and it is easier and pref erable to commit to memory the neuroanatomy of the brain stem

The great desirability of being able to categorize the majority of brain stem vascular cases hardly needs to be mentioned However an analysis of the authors personal experience with a large number of these cases shows that too often it has been impossible to either designate the vessel involved or fit the clinical picture to an eponym A survey of the literature indicates that complete neuro pathologic studies in this territory are so few that reliable rules for the exact identification of vessel or vessels involved are not available except for a few of the major syndromes described above There fore it seemed more practical to classify the cases according to the topography of the lesions within the brain stem and to this end the classification seen in Fig 197 was drawn up There are some twelve syndromes in all the principal eight being medial and lateral lesions at four different levels of the brain stem upper pons midpons lower pons and midmedulla Three are simple combinations of a few of the eight syndromes just mentioned while the final syndrome represents a full brain stem infarction This list of syndromes has been useful to the authors in cataloguing many of the day to day clinical cases but it must be appreciated that there are still many patients who do not fit the classification

Further Remarks Concerning Symptomatology In addition to the neurologic manifestations which can be assigned to one or another region of the brain many phenomena whose origin is still ob scure are to be encountered in stroke cases of all types The following remarks relate chiefly to in farction but for the most part they apply also to hemorrhage Cheyne Stokes respiration or a variant thereof is an extremely common finding especially with supratentorial lesions unilateral or bilateral Incontinence of bladder and/or bowel is a regular accompaniment of strokes of moderate to severe degree Vomiting a few times at the onset of a stroke is frequent Sucking and grasping reflexes are extremely common on the side opposite the hemiplegia i e the supposedly unaffected side the grasp reflex showing itself in several ways e g the patient s tendency to palpate rubber tubing or the folds of the bedclothes The temperature

Conversely, the early development of spasticity in the hand grasp reflex and other postural reactions may presage a favorable outcome Bowel and bladder continence usually returns as mental clarity is regained and sphincteric disorders persist only in patients with the most severe hemiplegia or bilateral motor lesions Not uncommonly the hemiplegic limbs are at first tender and ache on manipulation, hindering the physical therapy program Nevertheless physiotherapy should be initiated early in order to prevent fixation contracture at shoulder elbow wrist knuckles knee and ankle a frequent complication and often the source of pain and added disability An annoying unsteady dizzy feeling in the head often persists after damage to the vestibular system in brain stem infarcts

Recurrent cerebral (epileptic) seizures are a complication in some 20 per cent of cases of infarction in which the cerebral cortex has been involved They are infrequent during the period of onset of the thrombotic stroke and usually appear within a few weeks or months It is important not to construe the occurrence of a seizure as an indication of extension of the infarct

Many patients complain of fatigability and are depressed The explanation of these symptoms is uncertain psychologic factors may be important Only a few patients become serious *behavior problems* or psychotic after a stroke but paranoid trends ill temper stubbornness and peevishness are common

Finally in regard to prognosis it must be mentioned that having had one thrombotic stroke the patient is always in danger of another This is especially true in the presence of hypertension

Treatment of Cerebral Thrombosis The treatment of cerebrovascular disease and strokes may be divided into four parts (1) general medical management in the acute phase (2) measures to arrest the pathologic process and restore the integrity of damaged brain tissue (3) physical therapy and rehabilitation (4) preventive measures against strokes and vascular disease

General Medical Management in the Acute Phase In essence this is the care of the comatose or helpless patient (see Chap 272) *Maintenance of the airway* is of great importance The only real danger is pooling of secretions in the pharynx to avoid this the patient must be nursed on his side or in the semiprone position *Pharyngeal suction* is often necessary the larynx or trachea is touched by the tip of the suction tube to stimulate coughing A mouth airway as employed in administering anesthesia can be used if the patient is sufficiently stuporous to tolerate it In a more alert patient when the jaw is held tightly clenched and a nasal feeding tube is in position blocking one side of the nose respiratory exchange may be insufficient and a *tracheostomy* will have to be performed Especially is this necessary when coughing is impossible Oxygen therapy preferably by nasal tube is advisable if aeration of the lungs is compromised in any way *Prevention of pulmonary complications* is best achieved by turning the patient every hour, by strict avoidance of oral feeding if the slightest dysphagia exists and by the use of prophylactic penicillin therapy Constant urinary bladder drainage with daily irrigation regular changing of catheters and urinary antiseptics (Cantrisin in doses of 1 0 Gm per day) is necessary if coma is protracted Intravenous fluids for the first 2 to 3 days followed by transnasal stomach tube feedings are the best means of providing adequate fluid intake and nourishment Other measures include elastic stockings on the legs and correction of cardiac failure and its effects i e edema

Measures to Arrest the Pathologic Process and Restore the Integrity of Damaged Brain Tissue Most of the methods recommended in the handling of acute strokes due to infarction aim to dilate the cerebral arteries and enhance collateral blood flow to the region of brain softening Severely damaged brain tissue cannot be saved but it is suspected that the marginal zones of the infarct and even islands of tissue within the infarct have not been irreversibly injured but are merely receiving insufficient blood and oxygen to maintain normal function Improvement in the blood supply should therefore result in the restoration of function It is speculated also that widespread vasoconstriction or vasospasm occurs in association with sudden vascular occlusion and the use of vasodilators would counteract this aggravating factor (but see the following paragraph)

The following are the more important methods which have been or are being used (1) *Cervical sympathetic block* This procedure has fallen into disuse since careful clinical studies failed to confirm the initial reports of its beneficial effect (2) *Cerebral vasodilators* Despite experimental evidence that these agents increase the cerebral blood flow as measured by the nitrous oxide method they have not proved beneficial in careful studies in human stroke cases This is true of inhalation of 5 per cent carbon dioxide nicotinic acid Priscoline alcohol and papaverine A few clinical trials have indicated that histamine aminophylline and intra arterial papaverine have some merit but further investigation is needed In opposition to the use of these methods is the suggestion that vasodilators are harmful rather than beneficial since by lowering the systemic blood pressure the intracranial anastomotic flow may be reduced (3) *Measures to increase the blood supply to the brain* Clinical observations indicate that strokes and ischemic attacks in many cases develop when the patient gets

anterior cerebral stems However the procedure as practiced at present is not without risk and in patients with vessels narrowed by atherosclerosis the infarction may be extended It is not to be recommended as a routine measure in cerebral thrombosis but for the time being should be used only if the diagnosis of vascular disease is uncertain if vascular surgery is contemplated or as part of a scientific investigation of cerebrovascular disease Radioactive concentration studies (arsenic scan) used for the detection of tumor abscess etc often show a mildly positive picture over infarcts

Course and Prognosis In the introduction it was pointed out that the characteristic temporal profile of a vascular lesion was one of improvement if the patient survives When the patient is seen early in the course of his illness it is extremely difficult to generalize about the *immediate prognosis* This brings up the crucial question in cerebral thrombosis Where does the patient stand in the stroke process when he is first examined? Is worsening to be anticipated or not? No rules have yet been laid down which allow one to predict the course A mild paralysis today may become a disastrous hemiplegia tomorrow or the patient s condition may only worsen temporarily for a day or two In basilar artery occlusion dizziness and dysphagia may progress in a few days to total paralysis and deep coma The course of the deficit is so often progressive that a pessimistic attitude on the part of the physician is justified in what appears to be a mild case Extension of the thrombotic process is frequently mentioned as the cause of the progressive course of some strokes and this is probably true in some patients especially if there is involvement of the basilar artery Also in the carotid system thrombus at times propagates from the region in the neck where it started to the more distal suprachnoid portion and possibly into the anterior cerebral artery hindering anastomotic flow from the opposite side Or in middle cerebral occlusion retrograde thrombosis may occur back to the mouth of the anterior cerebral perhaps secondarily infarcting the territory of that vessel In many patients however extension of the thrombus is probably not the cause of the progression of the stroke and some of the ischemia modifying factors already referred to must be held responsible

Many other factors also contribute to the *immediate prognosis* in cerebral thrombosis In the case of large infarcts swelling of the infarcted tissue occurs tentorial herniation follows and the patient dies in 2 to 4 days On the other hand milder degrees of swelling and increased intracranial pressure though causing an apparent progression for 2 to 3 days may not prove fatal In extensive basilar infarction associated with deep coma the patient seldom lives for more than a few days If coma or stupor is present in a case from the beginning survival may be largely determined by the success in keeping the airways clear and maintaining fluid and electrolyte balance (see Chap 272) Respiratory and urinary infections are a constant danger and once they begin there is usually a rapid decline in the patient s condition coincident with the rise in temperature

As for the *eventual or long term prognosis* of the neurologic deficit caused by the stroke there are too many possibilities to recount them in detail In the case of small infarcts recovery may start within hours or a day or two and restoration may be complete In other cases there may be no significant recovery whatsoever and after months of assiduous efforts at rehabilitation the patient may remain bereft of speech with the upper extremity still totally useless and the lower extremity serving only as an uncertain prop in attempting to walk Between these two extremes there is every shade of recovery It is safe to say that the longer the delay before movement begins the poorer the prognosis becomes If recovery is not well started within 1 to 2 weeks the outlook is gloomy both for motor activity and speech and in general it may be said that whatever motor paralysis remains after 5 to 6 months will probably be permanent Sensory improvement has been detected for up to 2 years A hemianopia which has not cleared up in a few weeks will often remain permanently although reading color discrimination and object recognition may continue to improve Lateral medullary infarction might be regarded as an exception to the above rule for difficulty in swallowing may be protracted (4 to 7 weeks) and yet relatively normal function may be restored finally

The question of recovery after cerebral lesions raises the broad problem of the functional substitution of one part of the brain for another At present it is the consensus of opinion that one region does not take over the function of another unless those parts normally worked in close cooperation For example musculature which is subserved by both hemispheres e g the face eyes throat etc may resume functionally normal activity after an extensive hemispheral lesion It has not been proved that recovery from expressive or receptive asphasia is due to the assumption of speech function by the intact nondominant cerebral hemisphere since some part of the damaged speech areas will usually have escaped destruction

Characteristically the paralyzed muscles are flaccid in the first days or weeks following a stroke but gradually spasticity develops and the tendon reflexes become brisker The arm tends to assume a flexed adducted posture whereas the leg is usually extended and adducted Function is rarely if ever restored after the slow [illegible]

tion when in thrombotic cases worsening in the clinical picture is occurring from hour to hour or day to day

The use of anticoagulant drugs makes an accurate clinical diagnosis imperative Intracranial hemorrhage must be ruled out by relying primarily on examination of the cerebrospinal fluid it is to be remembered however that finding the fluid clear does not necessarily exclude hemorrhage (see p 1594) A control prothrombin concentration and coagulation time are desirable before therapy is started but if this is not feasible the initial doses of anticoagulant drugs can usually be given safely if there is no evidence of active bleeding anywhere in the body The question of whether or not severe hypertension is a contraindication to anticoagulant therapy has not been accurately answered There is no reliable evidence that complications are more frequent in the presence of hypertension and therefore the authors have not withheld anticoagulant therapy in these patients however when the diastolic blood pressure is in the range of 130 mm Hg or more an attempt is made at the same time to lower the pressure gradually with hypotensive agents exercising great care not to prejudice further the circulation in the region of the infarct by too great a reduction in the systemic pressure It would be preferable to avoid reduction of the blood pressure in the 2 week period immediately following a thrombotic stroke

Anticoagulant therapy is safe provided the prothrombin concentration is determined regularly (once a day for the first 10 days thence thrice a week and finally every week or 10 days) at a laboratory using reliable methods Therapy can be prolonged for months and years and only occasionally is it necessary to interrupt treatment because of unexplained disturbances of coagulation Dicumarol overdosage will cause hemorrhage from the kidney nose bowel skin or into muscle Although these accidents are usually not serious vitamin K_1 should be administered immediately

Prevention of a Stroke by Avoiding Situations in Which Strokes Are Likely to Occur (1) Particular care should be taken to maintain the systemic blood pressure oxygenation and intracranial blood flow during surgical procedures especially in elderly patients (2) hypotensive agents whether given therapeutically or for diagnostic procedures should be administered with great care (3) in the elderly patient in whom deep sleep might help to precipitate cerebral ischemia oversedation should be avoided (4) systemic hypotension severe anemia and polycythemia should be treated promptly

GENERAL The methods just discussed for the most part constitute delaying actions The ultimate solution of the problem lies in more fundamental fields Atherosclerosis and hypertension must be prevented or alleviated (see Chap 228 for prophylaxis of atherosclerosis and Chap 227 for the treatment of hypertension) Another factor possibly of great importance in contributing to vascular disease is the smoking of cigarettes the authors advise all patients with cerebral atherothrombotic disease to stop smoking Hypercoagulability of the blood has been suggested as the explanation for the fact that some atherosclerotic patients are more disposed to thrombotic episodes than others Correction of such an abnormality would be highly advantageous but at present there is no reliable method of detecting intravascular hypercoagulability if such a disorder exists

CEREBRAL EMBOLISM

In most cases of cerebral embolism the embolic material consists of a fragment which has broken away from a thrombus within the heart Embolism due to fat tumor cells or air is a rare occurrence and seldom enters into the differential diagnosis of strokes The embolus is usually arrested at a bifurcation or other site of narrowing of the lumen Ischemic infarction usually follows and is pale red or mixed No region of the brain is immune from attack but the territory of the middle cerebral artery is most frequently involved The two hemispheres are approximately equally affected Large embolic masses will block larger vessels (sometimes the carotids in the neck) while tiny fragments may reach vessels as small as 0 2 mm in which case the resultant infarct might be so small as to be easily overlooked at autopsy The exact behavior of embolic material is not fully known Although often perhaps in most cases it remains arrested and plugs the lumen solidly there is evidence that in many instances the embolus breaks up into fragments which enter smaller vessels or even disappear completely so that careful pathologic examination fails to reveal their final location The anatomic diagnosis must then be made by inference e g the absence of a vascular occlusion at the proper site

Cerebral infarcts vary greatly in the amount of congestion and hemorrhage found within the softened tissue Whereas some infarcts are strikingly pale others show mild or moderate congestion (dilatation of vessel and some extravasation of red blood cells) and still others show an extensive scattering of petechial hemorrhages throughout the damaged gray matter (red infarction) Emboli give rise to pale or red infarcts while thrombotic infarcts are usually pale i e red infarction is usually a sign of embolism The reason for the different coloration of softenings is not known although one hypothesis attributes it to the fragmentation and migration of embolic material from its original site of arrest the movement distally allowing blood to enter the part of the infarct lying more proximally

up from his bed particularly in the morning or postoperatively. In the upright posture the cerebral circulation falls, and for this reason it is recommended that patients with a stroke as the result of ischemic infarction should remain horizontal in bed for 7 to 10 days initially, and that when ambulation starts special attention should be given to preservation of the systemic circulation (the patient must avoid standing quietly for prolonged periods, must sit with the feet up, etc.). In stroke cases it is of great importance that the systemic blood pressure be maintained (correction of blood loss, use of Levophed in myocardial infarction with vascular collapse, avoidance of autonomic blocking agents, etc.). Injections of epinephrine have been recommended as a means of raising the systemic blood pressure above the usual levels. Although this enhances cerebral blood flow and could be beneficial, a systematic trial in thrombotic cases has not been undertaken. Anemia must be corrected. (4) Recently a few surgeons have undertaken to relieve arterial obstruction surgically. The procedures used include carotid thromboendarterectomy, resection of the carotid bifurcation with either insertion of a graft or a direct end-to-end anastomosis, arterial loop grafts to bypass an occluded portion of the carotid artery, and embolectomy. Some of these operations were performed in cases in which a stroke had recently developed; in others, they were carried out because of prodromal transient ischemic attacks. It has been impossible to evaluate the results. The operations themselves carry considerable risk.

Physical Therapy and Rehabilitation. Beginning within a few days, the joints of the paralyzed limbs should be passively carried through a full range of movement twenty to fifty times a day. Contracture shortening must be avoided, especially at the shoulder, elbows and ankle. Pain, soreness and aching in the paralyzed limbs may temporarily interfere with exercises. The patient can be placed in a chair after 2 weeks or so, depending on the severity of his illness. Nearly all hemiplegics can learn to walk again to some extent, usually within a 3- to 6-month period, and this should be a primary aim in rehabilitation. A long or short leg brace is often required. Speech therapy is of questionable value but should be tried. At least it is of value psychologically. Physical therapy seems not to benefit patients with cerebellar ataxia. As the hemiplegic patient improves and if mentality is preserved, instruction in the activities of daily living, using various special devices, can assist him in becoming at least partially independent in the home.

Preventive Measures against Strokes and Vascular Disease. Once a thrombotic stroke has developed fully, no therapy so far devised is of any value in restoring function. There is no need to emphasize the fact that prevention is the most important category of therapy. Preventive measures in cerebral thrombosis might be divided into special and *general*.

SPECIAL. *Prevention of a Thrombotic Stroke of Which There Has Been a Warning in the Form of One or More Transient Ischemic Attacks.* Many different therapies have been recommended: papaverine and phenobarbital, cervical sympathectomy, nicotinic acid, aminophylline, and breathing 5 per cent carbon dioxide in oxygen. However, each of these methods has failed in the hands of other workers. According to first reports, anticoagulant therapy promises both to prevent the ischemic episodes and to postpone indefinitely the arrival of an impending stroke, whether the carotid or basilar system is involved. However, further studies are necessary before anticoagulant therapy can be unequivocally recommended. Recently surgical procedures—carotid endarterectomy or carotid resection—have been undertaken in order to restore the cerebral circulation and prevent ischemic attacks. To date it has been impossible to evaluate the results.

Halting the Advance of a Progressive Thrombotic Stroke. This problem is closely allied to that just discussed and refers to strokes which are evolving in a stepwise fashion. Nicotinic acid, stellate block, and 5 per cent CO_2 inhalation are ineffective. At present, anticoagulant therapy seems to be the most effective measure, but is not successful in all cases. In trying to decide whether or not anticoagulant therapy is indicated, one faces again the crucial question in thrombotic strokes: Where in the course of his stroke does the patient stand when he is first examined? Will his course be benign or disastrous? Unfortunately no answers have yet been formulated.

Prevention of Repeated Strokes. Not infrequently one encounters patients in whom several separate, usually small, thrombotic strokes occur within a period of several months. Hypertension is usually present. Thus far anticoagulant therapy is the only measure recommended for the prevention of these recurrences, but its value has yet to be assessed (see Cerebral Embolism, p. 1558).

When *anticoagulant therapy* is instituted in stroke cases, Dicumarol or a drug of similar action is usually used. If an anticoagulant effect appears to be urgently required, heparin is administered concomitantly intravenously in doses of 50 to 75 mg every 3 to 5 hr until the Dicumarol becomes effective. Heparin can also be injected deep-subcutaneously in a dosage of approximately 100 mg every 6 to 9 hr as determined by coagulation tests. Dicumarol alone is sufficient in patients with transient ischemic attacks, repeated thrombotic strokes, or cerebral embolism (see p. 1558). [illegible]

tion when in thrombotic cases worsening in the clinical picture is occurring from hour to hour or day to day

The use of anticoagulant drugs makes an accurate clinical diagnosis imperative Intracranial hemorrhage must be ruled out by relying primarily on examination of the cerebrospinal fluid it is to be remembered however that finding the fluid clear does not necessarily exclude hemorrhage (see p 1594) A control prothrombin concentration and coagulation time are desirable before therapy is started but if this is not feasible the initial doses of anticoagulant drugs can usually be given safely if there is no evidence of active bleeding anywhere in the body The question of whether or not severe hypertension is a contraindication to anticoagulant therapy has not been accurately answered There is no reliable evidence that complications are more frequent in the presence of hypertension and therefore the authors have not withheld anticoagulant therapy in these patients however when the diastolic blood pressure is in the range of 130 mm Hg or more an attempt is made at the same time to lower the pressure gradually with hypotensive agents exercising great care not to prejudice further the circulation in the region of the infarct by too great a reduction in the systemic pressure It would be preferable to avoid reduction of the blood pressure in the 2 week period immediately following a thrombotic stroke

Anticoagulant therapy is safe provided the prothrombin concentration is determined regularly (once a day for the first 10 days thence thrice a week and finally every week or 10 days) at a laboratory using reliable methods Therapy can be prolonged for months and years and only occasionally is it necessary to interrupt treatment because of unexplained disturbances of coagulation Dicumarol overdosage will cause hemorrhage from the kidney nose bowel skin or into muscle Although these accidents are usually not serious vitamin K_1 should be administered immediately

Prevention of a Stroke by Avoiding Situations in Which Strokes Are Likely to Occur (1) Particular care should be taken to maintain the systemic blood pressure oxygenation and intracranial blood flow during surgical procedures especially in elderly patients (2) hypotensive agents whether given therapeutically or for diagnostic procedures should be administered with great care (3) in the elderly patient in whom deep sleep might help to precipitate cerebral ischemia oversedation should be avoided (4) systemic hypotension severe anemia and polycythemia should be treated promptly

GENERAL. The methods just discussed for the most part constitute delaying actions The ultimate solution of the problem lies in more fundamental fields Atherosclerosis and hypertension must be prevented or alleviated (see Chap 228 for prophylaxis of atherosclerosis and Chap 227 for the treatment of hypertension) Another factor possibly of great importance in contributing to vascular disease is the smoking of cigarettes the authors advise all patients with cerebral atherothrombotic disease to stop smoking Hypercoagulability of the blood has been suggested as the explanation for the fact that some atherosclerotic patients are more disposed to thrombotic episodes than others Correction of such an abnormality would be highly advantageous but at present there is no reliable method of detecting intravascular hypercoagulability if such a disorder exists

CEREBRAL EMBOLISM

In most cases of cerebral embolism the embolic material consists of a fragment which has broken away from a thrombus within the heart Embolism due to fat tumor cells or air is a rare occurrence and seldom enters into the differential diagnosis of strokes The embolus is usually arrested at a bifurcation or other site of narrowing of the lumen Ischemic infarction usually follows and is pale red or mixed No region of the brain is immune from attack but the territory of the middle cerebral artery is most frequently involved The two hemispheres are approximately equally affected Large embolic masses will block larger vessels (sometimes the carotids in the neck) while tiny fragments may reach vessels as small as 0 2 mm in which case the resultant infarct might be so small as to be easily overlooked at autopsy The exact behavior of embolic material is not fully known Although often perhaps in most cases it remains arrested and plugs the lumen solidly there is evidence that in many instances the embolus breaks up into fragments which enter smaller vessels or even disappear completely so that careful pathologic examination fails to reveal their final location The anatomic diagnosis must then be made by inference e g the absence of a vascular occlusion at the proper site

Cerebral infarcts vary greatly in the amount of congestion and hemorrhage found within the softened tissue Whereas some infarcts are strikingly pale others show mild or moderate congestion (dilatation of vessel and some extravasation of red blood cells) and still others show an extensive scattering of petechial hemorrhages throughout the damaged gray matter (red infarction) Emboli give rise to pale or red infarcts while thrombotic infarcts are usually pale i e red infarction is usually a sign of embolism The reason for the different coloration of softenings is not known although one hypothesis attributes it to the fragmentation and migration of embolic material from its original site of arrest the movement distally allowing blood to enter the part of the infarct lying more proximally

to explain the infarct the absence of atherosclerosis or other cause for thrombosis in the cerebral vessel a ready source of embolus infarcts in other organs such as kidney and spleen the occurrence of hemorrhagic infarction and last but not least the clinical history

Because of the rapidity with which emboli cause occlusion there usually is not time for collateral *influx to become established* Thus sparing of territory distal to the site of occlusion is not so common as in thrombosis However all the ischemia modifying factors mentioned under thrombosis are still operative and will influence the size shape and severity of the infarct

Brain embolism is essentially a manifestation of heart disease Many kinds of heart disease can be associated with embolism The commonest direct cause is *chronic atrial fibrillation* due to atherosclerotic or rheumatic heart disease the source of the embolus being mural thrombus deposited within the auricular appendage Atrial fibrillation due to other types of heart disease can of course also lead to embolism e g hypertensive congenital thyrotoxic syphilitic etc Embolism probably occurs also *during paroxysmal auricular fibrillation or flutter* but there is need for further exact documentation of such cases Mural thrombus deposited on the damaged endocardium overlying a myocardial infarct is the second most frequent source of cerebral emboli Emboli can also arise from atrial thrombus associated with severe mitral stenosis without atrial fibrillation Cardiac surgery especially valvoplasty may disseminate fragments of thrombus or particles of a calcified valve leaflet Subendocardial fibroelastosis idiopathic myocardial hypertrophy and cardiac tumors are rare causes of embolism

The vegetations of acute and subacute bacterial endocarditis being infected give rise to septic embolism which results in several different pathologic pictures in the brain In some cases the infarcts (they are usually multiple) do not differ from those due to uninfected emboli but in others tiny septic infarcts develop or in the case of acute bacterial endocarditis there may be miliary abscesses into which a small amount of hemorrhage may occur (focal embolic encephalitis) Mycotic aneurysm now seen infrequently is another complication of septic embolism and may be a source of intracerebral or subarachnoid hemorrhage

Marantic or nonbacterial endocarditis occasionally causes cerebral embolism and can produce a most baffling clinical picture especially when associated as it often is with carcinomatosis Paradoxic embolism can occur when an abnormal communication exists between the right and left sides of the heart or when both ventricles communicate with the aorta Thus embolic material arising in the veins of the lower extremity or indeed anywhere in the systemic venous tree can bypass the pulmonary circulation and reach the cerebral vessels

Other sources of embolic material are far less frequent (1) Mural thrombus deposited upon ulcerated atheroma in the arch of the aorta or in the carotid arteries may break loose and find its way into brain arteries A large plaque of atherosclerosis is frequently present in the carotid sinus and massage of the carotid sinus may dislodge mural thrombus deposited thereon with the production of a hemiplegia This is one of the reasons why carotid massage should always be carried out gently (2) Atheromatous material may be washed out of a large plaque in the aorta or carotid vessels and carried distally into the branches of the affected vessel (3) The pulmonary veins are a source of cerebral emboli as indicated by the occurrence of cerebral abscesses in association with pulmonary suppurative processes and by the high incidence of carcinoma of the brain secondary to pulmonary deposits (4) Surgery of the neck and thorax can be complicated by cerebral embolism A rare type is that which follows thyroidectomy in which thrombosis in the stump of the superior thyroid artery *extends proximally until a section of it protruding* into the lumen of the carotid is carried away into the cerebral arteries

Cerebral embolism must have occurred in every case in which secondary tumor is deposited in the brain likewise cerebral embolism must regularly accompany septicemia Rarely is the mass of tumor cells or bacteria large enough to occlude a cerebral artery and produce the picture of a stroke Nevertheless tumor embolism has been reported secondary to cardiac myomyxomas and occasionally with other tumors Embolism in the course of septicemia usually means that a vegetative endocarditis is present with thrombus formation Cerebral fat embolism is usually related to trauma As a rule the emboli are minute and widely dispersed and accordingly the clinical picture is usually not focal, as in strokes Cerebral air embolism is a rare complication of criminal abortion or of cervical and thoracic operations and was formerly encountered as a complication of pneumothorax therapy

Not infrequently at autopsy the diagnosis of cerebral embolism is made with full justification without finding a source The same is true of embolism elsewhere in the body Possibly the routine search for a thrombotic nidus is not sufficiently thorough and small thrombi in the auricular appendage the pulmonary veins or the endocardium between the papillary muscles of the heart may be overlooked Nevertheless in some cases studied most carefully no source of embolic material has been discovered

The Clinical Picture Of all strokes those due to cerebral embolism develop most rapidly Like a

bolt from the blue" the full blown picture evolves within several seconds or a minute exemplifying most strikingly the temporal profile of a stroke The clinical picture comes in a single sudden attack scarcely ever in stuttering fashion As a rule there are no warning episodes whatsoever These statements are possibly too stringent for in occasional cases the picture may take several hours to develop or a transient episode may precede the final arrival of the stroke However any emphasis on these few exceptions is entirely misleading The embolus strikes at any time of the day or night When the stroke develops during sleep its exact mode of development will not be known

The neurologic picture will depend on the artery blocked and where along its course the obstruction lies The syndromes related to each cerebrovascular territory are the same as those outlined under thrombosis (see p 1565 ff) A large embolus may plug the internal carotid artery or the stem of the middle cerebral artery producing a severe hemiplegia Or the embolus may be smaller and pass into one of the branches of the middle cerebral artery and produce a strikingly focal disorder motor aphasia a monoplegia (or part thereof) a receptive type of aphasia with little or no motor paralysis or a sensorimotor paralysis with little or no involvement of the supersensory zone It is important to realize that an embolus in its passage along an artery may temporarily compromise the local circulation with the production of a severe neurologic deficit which clears up almost as quickly as it came because the embolus finally passes into a branch supplying a relatively silent part of the hemisphere In other word embolism is one of the causes (and not an uncommon one) for a single evanescent stroke Embolic material entering the vertebral basilar system occasionally lodges in the vertebral artery just below its union with the basilar but more often the embolus traverses the vertebral and since the basilar artery is larger than the vertebral the embolus will not be held up until it reaches the upper bifurcation of the basilar artery If arrested here it abruptly produces deep coma and total paralysis More often the embolus enters one or the other posterior cerebral artery or both of them and by infarcting the visual cortex causes a unilateral or bilateral homonymous hemianopia It is rare for embolic material to enter the pontine vessels whereas embolic infarction of the under surface of the cerebellum is extremely common It has already been pointed out that recurrent transient ischemic attacks of the same pattern are not likely to be embolic since successive emboli could not be expected to lodge at identical sites

The more general neurologic disturbance associated with embolic strokes is not significantly different from that seen in thrombotic cases and the reader is referred to the description of the changes in consciousness respiration etc on p 1564 Again the patient may have a most devastating hemiplegia and yet be quite alert Headache is not uncommon

Although the abruptness with which the stroke develops and the lack of prodromal symptoms point strongly to embolism it is the total clinical picture upon which the diagnosis is based If hemorrhage is ruled out there remains only thrombosis to be excluded The presence of auricular fibrillation a history of myocardial infarction (recent or in the preceding months) or the occurrence of embolism to other regions of the body all support the diagnosis of embolism Embolism merits the most careful consideration in young persons in whom atherosclerosis is rather unlikely Not infrequently the first sign of myocardial infarction is the occurrence of embolism and therefore it is advised that an electrocardiogram be made in all cerebrovascular strokes of uncertain origin

Acute and subacute bacterial endocarditis do not usually present as a stroke due to infarction although this does happen occasionally The clinical signs of endocarditis anemia splenomegaly and often a pleocytosis in the cerebrospinal fluid should point to the correct diagnosis

The diagnosis of the other causes of cerebral embolism—cardiac surgery neck surgery pulmonary vein thrombosis marantic endocarditis paradoxic embolism tumor fat and air—will not be enlarged upon here

Laboratory Findings The description under thrombosis (p 1581) applies for the most part to embolism except in so far as hemorrhagic infarction and septic embolism (focal embolic encephalitis) are concerned Cerebral embolism commonly produces hemorrhagic infarction which in most instances does not cause the cerebrospinal fluid to be bloody However in some excessively hemorrhagic infarcts the fluid may be grossly bloody and contain as high as 10 000 or more red cells per cubic millimeter The pressure is relatively normal and this may help to distinguish the process from primary intracerebral hemorrhage In the milder cases of hemorrhagic infarction a slight xanthochromia (grade 1 to 2 on the scale of 1 to 10) may appear after a few days The possibility that embolic infarcts are unusually bloody indicates the danger of administering anticoagulants routinely in cases of cerebral embolism Also it necessitates caution in assuming that blood in the spinal fluid is unequivocal evidence that the stroke is due primarily to a hemorrhage

In the septic embolism of subacute bacterial endocarditis the white blood cells in the cerebrospinal fluid may number as high as several hundred but are usually less than 200 per cubic millimeter the proportion of lymphocytes and polymorphonu

clears varying with the acuteness of the septic process There may also be several hundred or more red blood cells and a faint xanthochromia is often present However a pleocytosis is not invariably seen in this condition The protein values are elevated and the sugar content is within normal limits No bacteria are seen or obtained by culture In acute bacterial endocarditis there may be either a frank purulent meningitis or the cerebrospinal fluid formula of subacute endocarditis

Course and Prognosis The remarks made concerning the *immediate prognosis* in cerebral thrombosis apply as well here Life is threatened in patients who have massive cerebral swelling made quite airway and respiratory or urinary infection As a rule all but the most aggravated cases survive the initial insult Massive brain stem infarction as a result of basilar embolism is almost always fatal The *eventual prognosis* as to survival is determined by the occurrence of further emboli and the gravity of the underlying illness cardiac failure rheumatic heart disease myocardial infarction bacterial endocarditis malignant growth etc The threat of an early recurrence of embolism is very real and it is not uncommon to have the second embolus strike within a few days or weeks of the first The urgency of anticoagulant therapy is thereby underlined The *eventual prognosis* regarding the neurologic deficit is not different from that given for cerebral thrombosis (p 1582) The fact that an embolic episode may last only minutes or hours before clearing up is to be emphasized especially in estimating the effect of any therapeutic measure

Treatment The first three phases of therapy—(1) general medical management in the acute phase (2) measures directed to restoring the integrity of damaged tissue and (3) rehabilitation—are the same as described under cerebral thrombosis (see p 1583) Occasional attempts at embolectomy from the middle cerebral artery have been made but unsuccessfully In the field of prophylaxis there is strong evidence that the use of long term anticoagulant therapy is effective in the prevention of embolism in cases of auricular fibrillation and myocardial infarction After cerebral embolism has occurred the question arises as to the necessity of delaying anticoagulant therapy for several days to avoid precipitating bleeding into a hemorrhagic infarct It is the authors practice always to perform a lumbar puncture first in order to rule out gross hemorrhage from the infarct If the cerebrospinal fluid is clear (this does not rule out a hemorrhagic infarct) the authors proceed with anticoagulant therapy since there is the constant danger of another embolus breaking away from the heart The authors have not encountered a case in which the use of anticoagulant drugs has seemed to increase the degree of hemorrhage within a hemorrhagic infarct indicating that such therapy is relatively safe Rare exceptions to this statement may be expected The use of anticoagulant therapy in cases of acute myocardial infarction including those judged to be in the "good risk" category is advisable In cerebral embolism associated with subacute bacterial endocarditis anticoagulant therapy is usually held to be contraindicated because of the danger of intracranial bleeding but this viewpoint is based on flimsy evidence Nevertheless caution is advisable in this matter and it is preferable to rely on a rapid sterilization of the blood stream

Valvoplasty and amputation of the auricular appendage have substantially reduced the incidence of embolism in rheumatic heart disease The need for special care in preventing emboli from entering the carotid arteries during the performance of cardiac valvoplasty is appreciated by all thoracic surgeons

OTHER CAUSES OF CEREBRAL INFARCTION

Reference to the classification IC will show that there are only a few causes of cerebral thrombosis other than atherosclerosis and fewer still that are important in the stroke picture *Venous thrombosis* (considered under VII) is a rather uncommon condition and rarely mimics a cerebrovascular stroke Arising in relation to extracranial and intracranial sepsis surgical operations parturition and chronic wasting illnesses particularly in children it can cause a relatively mild neurologic illness with raised intracranial pressure headache visual obscurations and focal seizures or on the other hand it can lead to extensive cerebral infarction and hemorrhage with grave neurologic manifestations

Systemic hypotension usually results in unconsciousness (syncope) without focal motor and sensory signs but in the presence of vascular narrowing from any cause weakness or numbness may be precipitated and if the state of vascular collapse persists for a sufficient length of time local infarction will occur distal to the point of stenosis It has already been mentioned that transient ischemic attacks and persistent strokes often develop under circumstances which suggest that a fall of the systemic blood pressure was the precipitating factor Hypotension occurs in simple faint acute blood loss myocardial infarction Stokes Adams syndrome traumatic and surgical shock cardiac arrest or anesthetic accident during surgery hypersensitivity of the carotid sinus reflex and in the several types of postural hypotension (idiopathic postsympathectomy tabetic diabetic with autonomic blocking agents with Serpasil and on getting up and around after surgical operations)

Arteriography occasionally results in cerebral infarction In some cases this is because of cerebral thrombosis but the pathogenesis of other cases requires further study *Arteritis* is no longer a common cause of cerebral thrombosis at least in North America owing to the present satisfactory treatment of syphilis This is to be contrasted with the period up to 10 years ago when meningovascular syphilis had to be seriously considered in every stroke case "hemiplegia in the young" especially was strongly indicative of syphilis Necrotizing or granulomatous arteritis whether limited to the cerebral vessels or occurring as part of a polyarteritis has usually produced a slowly progressive neurologic deficit and has only rarely mimicked a stroke Idiopathic giant cell arteritis involving the large arteries arising from the aortic arch is a rare cause of unilateral or bilateral carotid occlusion but must be kept in mind It appears to be much more common in young women in Japan the aforementioned Takayasu s syndrome or "pulseless disease Cranial arteritis or temporal arteritis is almost always limited to the extracranial arteries except for the small vessels supplying the optic and oculomotor nerves Unfortunately in over 50 per cent of cases permanent blindness or a severe impairment of vision results When the process has involved the internal or common carotid arteries it has usually not caused a stroke (see p 1708 Chap 264)

Polycythemia sickle-cell disease and *thrombotic thrombopenia* are stated to be causes of cerebral thrombosis but further study of the matter is required A *dissecting aortic aneurysm* may involve the large vessels arising from the arch and result in carotid occlusion and hemiplegia a concomitant fall in systemic blood pressure probably contributing to the picture *Carotid occlusion* may be the result of direct *trauma* to the neck or it may be precipitated by a "closed head injury sometimes of a seemingly trivial nature *Hypoxia* usually produces a diffuse destruction of neurones rather than frank infarction but bilateral softening of the globus pallidus is a classical feature *Tentorial and subfalcial herniation* and sometimes cerebellar pressure can cause infarction by compression of the posterior and anterior cerebral and inferior cerebellar arteries respectively Under the rare types of infarction it should be mentioned that carotid occlusion has been described following *tonsillectomy* in association with *cavernous sinus thrombophlebitis* and the *trigeminal ganglionitis of herpes zoster* Also a previously transient and harmless migrainous aura is occasionally transformed into a persistent deficit presumably because of infarction as the result of excessive ischemia This complication most frequently takes the form of a homonymous hemianopia Finally a category for *cerebral infarction of undetermined cause* is included for it must be admitted that in some cases even at neuropathologic examination it is impossible to determine the exact cause of an infarct

Omitted from the classification is *Binswanger s chronic progressive subcortical encephalitis* a rare disease of cerebral white matter tentatively attributed by Binswanger to atherosclerosis The status of the disease is uncertain at present, and further investigation of the problem is warranted before the disease can be accepted as a separate entity

RECURRENT FOCAL CEREBRAL ISCHEMIA

It has already been pointed out that when transient ischemic attacks precede a stroke they stamp the process as thrombotic Furthermore neuropathologic studies indicate that these attacks are linked almost exclusively to atherosclerotic thrombosis although further data on this point are desirable They belong therefore under the heading of cerebral thrombosis but a separate category has been formed for them because of their importance clinically and therapeutically Recurrent ischemic cerebral attacks consist of recurrent transient episodes of focal cerebral disturbance e g weakness numbness dizziness etc and are most commonly encountered in the days or weeks preceding the onset of a thrombotic stroke occurring as a sort of a warning that disaster threatens In recent years increasing attention has been directed to these attacks with the purpose of preventing the arrival of the threatening stroke by administering anticoagulant drugs at the stage of prodromal symptoms There would seem to be little doubt that they are due to transient focal ischemia and they might be referred to as temporary strokes which fortunately reverse themselves Corresponding to the higher incidence of atherosclerosis in hypertension and in the male population about two-thirds of all patients with transient ischemic attacks are men and/or hypertensive

The Clinical Picture Transient ischemic attacks can occur by themselves or they may precede accompany or follow the development of a stroke So far it has not been possible to distinguish the early cases destined to do well from those in which a full blown stroke will develop Thrombosis of virtually any cerebral or cerebellar artery deep or superficial can be associated with transient ischemic attacks e g common carotid internal carotid middle cerebral anterior cerebral ophthalmic vertebral, basilar posterior cerebral the cerebellar arteries and the penetrating branches to the deep structures of the basal ganglions and brain stem If the posterior cerebral arteries are included in the vertebral basilar system ischemic episodes are

slightly more common in that system than in the carotid system

The neurologic features of the transient episode indicate the territory or artery involved and are fragments borrowed from the stroke which often is approaching. In the carotid system the episodes commonly take the form of unilateral weakness or numbness of the side of the body opposite the lesion. The entire side may be involved or the parts in various combinations face and lips or lips and fingers fingers alone hand and foot etc. Other manifestations include aphasia difficulty in calculation and other temporal parietal occipital functions (when the dominant hemisphere is involved) confusion veering to one side transient monocular blindness or blurring of vision scintillating scotomas headache and possibly focal epileptic seizures. Lack of pulsation in the carotid artery in the neck or pharynx reduced pressure in the appropriate central retinal artery and a contralateral cranial bruit indicate carotid occlusion

The clinical picture in the vertebral basilar system is exceedingly diverse since so much motor and sensory traffic is sustained by the blood carried in these vessels. Occurring in the most varied combinations the following manifestations may be recognized (the more common ones are italicized) *weakness* of part or all of one side of the body or both sides *numbness* of part or all of one side or both sides or crossed numbness (one side of face and opposite limbs) *dizziness diplopia* (vertical or horizontal) dark vision *blurred vision* tunnel vision partial or complete blindness scintillating scotomas pupillary change ptosis paralysis of gaze *dysarthria speechlessness dysphagia staggering gait* veering to one side *headache* noise or pounding in the ear or in the head head or face pain peculiar head sensations vomiting hiccoughing memory lapse confused behavior drowsiness unconsciousness (rare) impaired hearing deafness a feeling of movement of a part sweating and facial redness

It is not always easy to identify the territory affected. However the occurrence of receptive or sensory aphasia always points to the carotid system as does monocular blindness with or without contralateral numbness or weakness. The hallmarks of vertebral basilar involvement are (1) bilateral weakness and/or numbness i e a disturbance of the long motor or sensory tracts bilaterally (2) involvement of the infranuclear portion of one or more cranial nerves (3) disturbance of other segmental structures i e posture equilibrium ocular and visceral mechanisms. Perioral numbness is a not infrequent complaint and the patient often is not certain whether it is equally bilateral bilateral with unilateral preponderance or mostly unilateral with spread slightly to the other side of the midline. Diplopia and whirling dizziness are of particular importance in localization for they are rarely if ever associated with occlusion of the carotid system. Unilateral weakness and unilateral numbness as isolated phenomena are difficult to localize since they can occur in both carotid and basilar occlusion

The following manifestations are either very rare or may not occur at all in ischemic attacks unconsciousness convulsive movements fecal or urinary incontinence facial pallor formed hallucinations and the manifestations of temporal lobe seizures

Transient ischemic attacks last from a few seconds up to several hours the most common duration being a few seconds up to 5 to 10 min. It is uncommon for recurrent discrete attacks to last more *than 30 min. There may be only a few attacks or* several hundred. Between attacks the neurologic examination may disclose no abnormalities. A stroke may ensue after the second episode or may be postponed until hundreds have occurred over a period of weeks or months. Not infrequently the attacks gradually cease and no important paralysis occurs a fact which makes any form of therapy difficult to evaluate. The attacks may all take ap*proximately the same pattern or they may* vary considerably in detail although maintaining the same basic pattern. For example weakness or numbness may involve fingers and face in some episodes and fingers only in others or dizziness alone may occur in some attacks while in others diplopia is added to the picture. In basilar artery disease each side of the body may be affected alternately. All the involved parts may be affected simultaneously or a definite march or spread from one region to another can occur in a period of 10 to 60 sec or even as long as several minutes e g numbness may spread from the hand to the face or the reverse. The attacks may cease abruptly or fade gradually

The onset of attacks in some patients is clearly related to standing up after lying or sitting. In general attacks are likely to occur when the patient is up and around rather than lying down but in many cases the episodes bear no relation to position or activity. They have been encountered in relation to exercise exertion emotional outbursts of anger or joy and during bouts of coughing. Transient symptoms present on awakening from sleep usually indicate that a stroke is in the offing

Ophthalmoscopic observations of the retinal vessels made during episodes of transient monocular blindness show arrest of the blood flow in the retinal arteries and breaking up of the venous column to *form the well known box car pattern*. This could well indicate that in ischemic attacks elsewhere a temporary complete or relatively complete cessation of blood flow occurs locally

The pathogenesis of transient ischemic attacks is still not clear. In the past they have been attributed

to cerebral vasospasm or to transient episodes of systemic arterial hypotension with resulting compromise of the intracranial circulation Neither of these factors has been established Although dropping the blood pressure to 90 or even 80 mm Hg by tilting the patient on a tilt table into an upright position may cause EEG changes it has not in the authors experience reproduced the attacks Vasodilator drugs have been without effect There is increasing evidence that the attacks are abolished by anticoagulant drugs but the mechanism of this is not known Whatever their exact cause they are closely related to vascular occlusion due to thrombosis A proper recognition of the transient ischemic episode is of importance since the use of anticoagulant drugs may prove of value in warding off an oncoming stroke

The differential diagnosis of recurrent cerebral ischemic attacks raises special problems The following conditions must be differentiated cerebral seizures (epileptic seizures) Menieres syndrome paralytic migraine Stokes Adams attacks hypersensitive carotid sinus reflex akinetic falling spells of the aged and recurrent cerebral embolism

Frank motor convulsions rarely if ever occur in ischemic attacks The patient may report a feeling of movement distortion or drawing but jerking or twitching has not been encountered On the other hand a cerebral seizure rarely if ever displays as its only manifestation a temporary paralysis of a limb or of one side of the body Unconsciousness *is rare in ischemic attacks and its occurrence even* in only a few attacks indicates a seizure phenomenon Incontinence of bowel and bladder tongue biting cyanosis and residual sleepiness or muscle soreness are indicative of a seizure rather than an ischemic episode In the sensory sphere the distinction between ischemic episodes and seizures is less clear for numbness or scintillating visual phenomena are seen in both conditions and therefore the presence of associated phenomena (dizziness diplopia etc) must be relied on in making a differentiation When numbness appears simultaneously in face hand and leg i e when there is no march ischemia rather than a seizure is probably responsible When a *sensory march* occurs it will not serve to distinguish the two for while it is more characteristic of a seizure it may also occur *in ischemic episodes However in the latter its* spread is often slower in terms of minutes rather than seconds

The type of dizziness associated with brain stem ischemia has no characteristics which allow it to be distinguished from that seen in Menieres syndrome or labyrinthitis Therefore in making a diagnosis one depends on the presence of certain associated symptoms and signs It is a simple matter to decide that the dizziness is of central origin when there are other evidences of brain stem involvement by history or on neurologic examination diplopia numbness weakness dysphagia dysarthria cerebellar ataxia vertical nystagmus persistent horizontal nystagmus etc On the other hand the isolated presence of the triad of recurrent dizziness *tinnitus and chronic deafness (i e signs of both* auditory and vestibular involvement) is almost certain evidence of Menieres syndrome However the pictures at times resemble each other closely and only an especially thorough search will reveal signs indicating that the disorder is due to ischemia of the brain stem Tinnitus of a constant hissing or ringing type is a rare complaint in brain stem vascular disease When dizziness is the sole symptom in an elderly person it is often impossible to make an accurate diagnosis and only after observing the patient for a period of time will the nature of the underlying disease be disclosed Finally it must be remembered that since both basilar artery disease *and Menieres syndrome are common in this age* group the two conditions may coexist

The visual sensory and motor phenomena which precede the headache in some cases of migraine bear a close resemblance to ischemic manifestations but since migraine originates in early life only occasionally does its differentiation from ischemic attacks pose any problem When vascular disease has its onset during the period of life when migraine is prevalent the two may be confused until the history is carefully taken Occasionally a *migrainous paralytic aura returns after a headache* free interval of 10 to 20 years It has already been pointed out that headache at times of great intensity *frequently* accompanies cerebral thrombosis therefore in the elderly person the occurrence for the first time of periodic headache associated with scintillations or numbness should always suggest atherothrombosis rather than migraine *Stokes Adams attacks* and *hypersensitivity* of the *carotid sinus reflex* cause collapsing spells" with unconsciousness confusion and jerking but almost never do they produce focal neurologic manifestations such as numbness weakness diplopia etc Difficulty in differentiation of these conditions will arise only when the clinical details *of the episode are not* available and usually a careful minute by minute description of the attack will enable the correct diagnosis to be reached *Only in an occasional* case of basilar artery insufficiency will an ischemic episode result in unconsciousness usually accompanied by other symptoms such as weakness numbness blindness or dysarthria In *akinetic falling spells of the aged* a rather vague entity the patient falls unconscious without convulsive movements color change or alteration in pulse blood pressure or respiration Within a minute or two consciousness is restored

Cerebral embolism is frequently suggested as an explanation for recurrent cerebrovascular episodes However this seems unlikely if all the attacks are of identical pattern for successive emboli coming from a distance could not be expected to enter the same arterial branch Moreover the involved cerebral tissue would be at least partially damaged leaving some residual signs When only a single transient episode has occurred the factor of recurrence does not assist in the diagnosis and cerebral embolism must then be strongly considered

Treatment The therapy of transient ischemic attacks has already been discussed under cerebral thrombosis (p 1583) where it was pointed out that the administration of anticoagulant drugs usually stops the attacks and prevents indefinitely the onset of a threatening stroke Since in many patients the attacks cease spontaneously it would be desirable to have the indication for anticoagulant therapy more clearly set down However at present it is not possible to predict the course of recurrent ischemia and only tentative directions for anticoagulant therapy can be offered If the attacks are becoming more frequent more severe or of longer duration or if each attack no longer clears away completely and a persistent neurologic deficit is accumulating anticoagulant drugs are indicated When the episodes are few and spaced at long intervals further observation is warranted

Other measures that have been recommended include administration of phenobarbital papaverine or nicotinic acid inhalation of 5 per cent carbon dioxide breathing into a paper bag and stellate block or cervical sympathectomy but none of these has proved effective under careful clinical testing On several occasions the authors have been impressed with the salutary effect of having the patient stop smoking cigarettes For the more general therapeutic measures applicable in these cases see pp 1583 to 1586

HYPERTENSIVE INTRACEREBRAL HEMORRHAGE

Although 12 different causes of intracranial hemorrhage have been listed in the classification the first two hypertensive intracerebral hemorrhage and ruptured saccular aneurysm are much more important than the others and account for most of the hemorrhages which give rise to the clinical picture of a stroke Duret hemorrhages hypertensive encephalopathy and idiopathic brain purpura will not simulate a stroke and are included only for the sake of completeness

Hypertensive intracerebral hemorrhage is the ordinary well recognized brain hemorrhage Generally speaking the higher the blood pressure the more likely it is for hemorrhage to occur and though in some cases the levels are only in the range of 160 to 170/90 in most cases they are much higher The hemorrhage occurs within brain tissue and rupture of the arteries lying in the subarachnoid space is practically unknown apart from aneurysms It is a mistake to think of hypertensive hemorrhage as arising from the large arteries at the base of the brain The extravasation which results from rupture of an artery forms a roughly circular or oval mass which grows in volume as the bleeding continues Adjacent brain tissue is displaced and compressed If the hemorrhage is large midline structures are shifted to the opposite side and vital centers are compromised leading to coma and death Rupture or seepage into the ventricular system usually occurs and the spinal fluid becomes bloody in more than 90 per cent of cases A hemorrhage of this type almost never ruptures directly into the subarachnoid space through the cortex When the hemorrhage is small and placed at a distance from the ventricles the cerebrospinal fluid may remain clear even on repeated examinations

In order of frequency the commonest sites for hemorrhage are (1) the putamen and adjacent internal capsule (40 per cent of cases) (2) thalamus (3) cerebellar hemisphere (4) pons and (5) various parts of the central white matter (frontal lobe corona radiata etc) The vessel involved is usually a small penetrating artery The nature of the vascular lesion which leads to arterial rupture is not known and indeed the site of the rupture has not often been identified Atherosclerosis is held by many to be a factor but there is no proof for this view and hemorrhages are encountered in the absence of grossly visible atherosclerosis Small aneurysmal dilatations were reported by Charcot and Bouchard to be the basis for the rupture They may be responsible for hemorrhage in some instances but their occurrence only in arterioles and frequently in the cerebral cortex makes it unlikely that they explain many of the massive cerebral hemorrhages Hyalinosis of the small arteries due to hypertension has also been described as the precursor of hemorrhage Another hypothesis attributes the hemorrhage to a confluence of myriads of smaller diapedetic hemorrhages rather than a single extravasation but this is entirely without grounds and represents a confusion of hemorrhagic infarction and massive hemorrhage

Hemorrhages might be classified as massive small slit and petechial "Massive" refers to huge hemorrhages several centimeters in diameter "small" to those 1 to 2 cm in diameter slit applies to a special type of hypertensive hemorrhage which lies subcortically at the junction of white and gray matter and which in the healing stage becomes narrowed to an orange slit

The Clinical Picture The clinical picture conforms accurately *to the temporal profile of a cerebrovascular stroke* viz it has an abrupt onset and rather rapid evolution The stroke usually evolves *with gradualness* (not so suddenly as in embolism) taking minutes hours or occasionally days (average of 1 to 6 hr) to reach its peak depending on the speed of bleeding As a rule there are no recognizable warning or prodromal symptoms the patient being stricken out of the blue" Often the patient has been astonishingly well and headache dizziness and epistaxis have not occurred with any consistency as prodromal symptoms In the great majority of cases the hemorrhage comes on while the patient is up and active and onset during sleep is a great rarity Hypertension is by definition always present and the elevation is maintained early in the course of the stroke or may even rise higher so that the existence of hypertension will be easily established when the patient is first examined There is usually only one episode of hemorrhage and recurrent episodes of bleeding from the same site such as occur in cases of saccular aneurysm are not encountered Once bleeding has become arrested rebleeding in the near future that is after the first few days is not to be anticipated The neurologic deficit is never transitory in intracerebral hemorrhage as it so often is in thrombosis and embolism Once blood is spilled into the tissues it is removed only slowly over a period of weeks and months during which time symptoms and signs persist For the same reason rapid fluctuations in the neurologic deficit from one examination to another are not to be expected Cerebral seizures focal or generalized are not so rare at the onset of hemorrhage as at the onset of infarction and occur in the first few days in about 10 per cent of cases (not including attacks of "decerebrate rigidity")

The neurologic signs and symptoms vary with the site and size of the extravasation The commonest picture is that associated with a putaminal or thalamic hemorrhage in which the adjacent internal capsule is implicated The patient suddenly complains of something going awry within the head In a few minutes the face sags on one side speech becomes slurred or aphasic the arm and leg gradually weaken and the eyes tend to deviate away from the side of the paretic limbs A carefully taken history often reveals that these events occurred gradually over a period of 5 to 30 min This type of evolution is virtually diagnostic of intracerebral bleeding Gradually the paralysis worsens the affected limbs become flaccid pinprick is not appreciated a Babinski sign appears speaking becomes impossible and confusion gives way to stupor In the worst cases when blood enters the ventricular system under high pressure coma supervenes There is then a Babinski sign bilaterally respirations become labored deep irregular or intermittent *extensor rigidity occurs the pupils dilate and the* patient dies within a period varying from a few hours up to 24 or 48 hr This unfortunately is the course in over half the cases Respiratory failure nearly always precedes circulatory failure just as it does with all diseases of the brain but late in the course the blood pressure may fall A stroke is rarely the cause of sudden death unless it accompanies cardiac or respiratory disease However not all hemorrhages prove fatal and at any point bleeding may stop and if vital structures have not been irreversibly damaged the patient will survive (15 to 30 per cent of cases) The patients who do not lose consciousness stand the best chance of recovery Some patients live only for 4 to 7 days losing ground each day possibly because of a slow continuance of the bleeding It was formerly taught that when a hemorrhage had ruptured into the ventricular system deep coma was invariable Although this is a useful rule of thumb for contrasting brain hemorrhage with ruptured aneurysm where consciousness is more frequently preserved with grossly bloody cerebrospinal fluid there are many exceptions in which the patient is sufficiently alert to respond clearly to questions and commands

In cerebellar hemorrhage vertigo vomiting and ataxia appear first soon followed by coma if the outcome is to be fatal When the hemorrhage is in the pons consciousness is lost rather promptly and death usually occurs within a few hours But in each of these sites the hemorrhage may be arrested and the patient may recover A small cerebellar hemorrhage in particular can present a knotty clinical problem with few or no localizing signs other than a severe disequilibrium which precludes walking or even sitting up for several weeks Persistent dizziness and headache may be associated

Other findings help in the diagnosis of hypertensive brain hemorrhage Vomiting at the onset is the rule A severe headache is often but by no means always present if the patient s mental state permits the appreciation of discomfort Mild to moderate nuchal rigidity will be present but as coma deepens the neck becomes supple again Coma stupor and drowsiness are likely to be much more in evidence in hemorrhage than in cases of infarction In general the existence of a massive hemiplegia in the presence of a relatively well preserved sensorium and alertness speaks against hemorrhage and in favor of infarction

Many of the unlocalized neurologic manifestations described under cerebral thrombosis are also encountered in intracerebral hemorrhage including coma stupor drowsiness confusion delirium Cheyne Stokes respiration grasping and sucking reflexes incontinence of bowel and bladder and unilateral and bilateral extensor rigidity The fundi

often show hypertensive changes in the arteries and occasionally fresh preretinal hemorrhages occur although the latter are much more common in ruptured aneurysm or angioma Grade 4 hyper tension (malignant) with papilledema need by no means be present for cerebral hemorrhage to occur

There is no sex or age predilection except that intracerebral hemorrhage rarely occurs under the age of twenty Hypertension is usually of the "essential type but other causes must always be considered—renal disease pheochromocytoma ACTH overdosage injection of excessive amounts of epinephrine and rarely violent exertion or an intense emotional experience Cardiomegaly is usually present

Although the proper interpretation of this array of clinical data allows the correct diagnosis to be established in most cases the examination of the cerebrospinal fluid for blood is the most important aid in the detection of intracranial bleeding

Laboratory Findings Any urinary abnormalities will for the most part reflect coexisting renal disease although transient glycosuria has been re*ported to result specifically from intracranial hem*orrhage The white blood cell count often rises to 15 000 to 20 000 a higher figure than in thrombosis The sedimentation rate is elevated In cases of massive hemorrhage the cerebrospinal fluid is under increased pressure and grossly bloody although usually not so bloody as in ruptured saccular aneurysm (red cell count of 5 000 to 30 000 per cubic millimeter) In smaller hemorrhages into central structures the cerebrospinal fluid usually contains a lesser amount of blood and in occasional cases of intracerebral hemorrhage particularly in those of the "slit" type between cortex and white matter it remains free of blood and clear of xanthochromia despite repeated taps In these latter cases slight xanthochromia may appear after a few days to a week At times the spinal fluid may contain only some 400 red cells and it is then difficult to decide if this reflects intracranial bleeding or represents a traumatic tap These details are mentioned because they are of importance in the essential task of making an accurate diagnosis of the type of stroke prior to the use of therapeutic measures such as anticoagulant drugs surgical exploration hypothermia etc *A traumatic bloody spinal tap* greatly complicates the diagnostic problem and must be avoided In a bloody tap the pressure is normal or low the fluid that first flows from the needle is more bloody than that which comes later the fluid often clots in the test tube and xanthochromia is either absent or at most present only in proportion to the amount of serum bilirubin admixed with the fluid The bloody fluid due to cerebral hemorrhage is usually under increased pressure there is an even admixture of blood in all samples the cerebrospinal fluid will not clot and if more than a few hours have elapsed since the hemorrhage a definite xanthochromia will be present in the supernatant fluid after centrifugation which should always be carried out if there is any question of the reliability of the tap However the presence of xanthochromia after centrifugation may be due to the bilirubin contained in the blood spilled by a traumatic tap and therefore is not an infallible index of subarachnoid or brain hemorrhage The white blood cells of the cerebrospinal fluid are accounted for by the amount of hemorrhage and their ratio to red cells is usually the same in the circulating blood After hemolysis of red blood cells the white cell count in the cerebrospinal fluid may be disproportionately increased

Lumbar puncture is not completely innocuous since temporal lobe or cerebellar herniation may be aggravated in cases of massive supratentorial hemorrhage or softening and in cerebellar hemorrhage Despite this danger the procedure is necessary if specific therapeutic measures are contemplated or if any doubt exists as to the diagnosis of cerebro*vascular disease X ray of the skull early in the* stroke may show a shift of the calcified pineal gland to the side of the cranium opposite the lesion a change not seen in most infarcts The electroencephalogram does not show a typical or diagnostic pattern but high voltage slow waves are the commonest finding with hemorrhages in the cerebral hemisphere X ray of the chest will often show cardiomegaly and after coma has persisted for a time there may be pulmonary congestion and edema possibly attributable to neurogenic influences

Course and Prognosis The immediate prognosis is grave some 75 per cent of cases dying in 1 to 10 days Either the hemorrhage ruptures under pressure into the ventricular system or temporal lobe herniation and midbrain compression occur Sometimes the hemorrhage appears to seep gradually into vital centers Gastric erosion and gastrointestinal hemorrhage of neurogenic origin may occur at any time within the first week or two When the hemorrhage is smaller survival is possible and the restitution of motor function speech etc can be excellent since in contrast to infarction the hemorrhage pushes brain tissue aside instead of destroying it Function may be slow to return because extravasated blood is slow to be resorbed or removed from the tissues Since rebleeding from the same site is unlikely *the patient may live for* many years In some instances of medium sized cerebral hemorrhages the patient survives and his condition gradually stabilizes but definite papilledema appears after several days of increased intracranial pressure

Treatment *The general medical management of the comatose apoplectic patient is the same as that outlined under thrombosis* Measures to stem the hemorrhage and restore the integrity of damaged tissue have been relatively ineffective up to the present *Surgical removal of the clot* in the acute stage either by aspiration or evacuation has seldom proved successful In the smaller hemorrhages that reach a subacute stage papilledema may appear and has in many instances dictated a surgical evacuation of the hemorrhage when the patient s condition stabilized Under these circumstances the operative procedure has been more successful although the prognosis is probably little improved by surgery Attempts to halt the hemorrhage by lowering the systemic blood pressure through the use of autonomic blocking agents have not been effective and in many instances the inadvertent occurrence of disastrously low levels of blood pressure has complicated the illness Recently artificial hypothermia has given promise of increasing the survival rate but there are insufficient data to permit appraisal of this difficult procedure

The *only preventive measure* is to lower the blood pressure in cases of essential hypertension by every possible means If ACTH or one of the adrenal steroids is being given toxicity must be watched for When hypotension threatens during surgical procedures injections of excessive amounts of epinephrine or ephedrine must be avoided

RUPTURED SACCULAR ANEURYSM

This is the fourth most frequent of the cerebrovascular disorders and presents one of the most disputed therapeutic problems of the day Saccular aneurysms take the form of small thin walled blisters protruding from the arteries of the circle of Willis or the major branches arising therefrom These saccules or berries as they have been called are located for the most part at bifurcations and branchings and are presumed to be the result of developmental defects in the media and elastica at these sites A small number of aneurysms have been attributed to incomplete involution of embryonic vessels Owing to the local weakness the intima bulges outward covered by adventitia the sac gradually enlarges until finally dissolution of the wall and rupture occur These saccular aneurysms vary in size from tiny nubbins 2 mm in diameter up to spherical masses 2 or 3 cm in diameter an average diameter is 8 to 10 mm Aneurysms vary greatly in form some being round and connected to the parent artery by a narrower stalk others are broad based without a stalk and still others are narrow cylinders The dome of the aneurysm may present one or more secondary sacculations In routine autopsies the incidence of ruptured aneurysms is 1 8 per cent of unruptured aneurysms 2 0 per cent

Saccular aneurysms are rare in childhood even at routine post mortem examination and increase in frequency to reach their highest plateau of incidence in the age period of thirty five to sixty five years Therefore they are not congenitally formed anomalies but develop over the years on the basis of a developmental arterial defect There is an increased incidence of congenital polycystic disease of the kidney and of coarctation of the aorta in association with saccular aneurysm Hypertension is more frequently present than in the average population but aneurysms occur in persons with perfectly normal blood pressure Atherosclerosis although present in the walls of about 50 per cent of aneurysms probably plays no part in their formation or enlargement

Eighty five to ninety per cent of saccular aneurysms lie on the anterior part of the circle of Willis The four commonest sites are (1) in relation to the anterior communicating artery (2) at the origin of the posterior communicating artery from the stem of the internal carotid (3) at the first major bifurcation of the middle cerebral artery and (4) at the bifurcation of the internal carotid into middle and anterior cerebral arteries (see Fig 198) Other sites include the internal carotid in the cavernous sinus at the origin of the ophthalmic artery at the junction of the posterior communicating artery with the posterior cerebral at the bifurcation of the basilar artery and at the origins of the three cerebellar arteries In 8 per cent of cases there is more than one aneurysm and they can involve one or both sides of the cerebral circulation[5]

The Clinical Picture Prior to rupture saccular aneurysms are usually asymptomatic and rarely cause even headache Occasionally large aneurysms immediately distal to the cavernous sinus may compress the optic nerves or chiasm the third nerve hypothalamus or pituitary gland In the posterior fossa one or more of the cranial nerves may be compressed as they leave the brain stem

When rupture occurs blood under high pressure *is discharged into the subarachnoid* space (the circle of Willis lies in the subarachnoid space) and

[5] Several types of aneurysm other than saccular occur e g mycotic fusiform diffuse and globular The last three are named for their predominant morphologic aspects and consist of enlargement or dilatation of the entire circumference of the involved vessels usually the internal carotid ertebral, or basilar arteries Frequently showing atherosclerotic *deposition in their walls* they are often referred to as arteriosclerotic, but most likely they are developmental in nature They rarely rupture but instead press on neighboring structures or become occluded by thrombosis

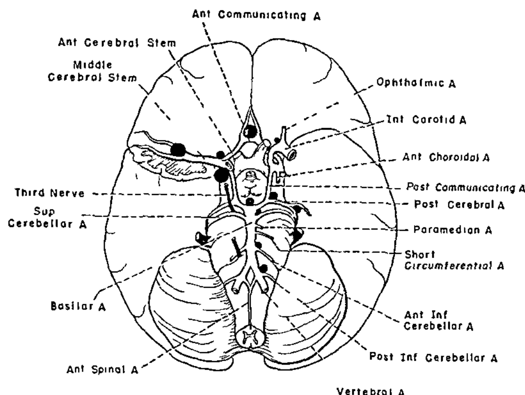

FIG 198 Diagram of the circle of Willis to show the principal sites of saccular aneurysm Approximately 90 per cent of aneurysms are on the anterior half of the circle

the resulting clinical events follow one of three courses (1) the patient may be stricken with an excruciating generalized headache and fall unconscious almost immediately (2) headache may develop as in (1) but the patient remains relatively lucid (3) consciousness may be lost quickly without any preceding complaint Convulsive seizures occur at the onset or during the first week following the hemorrhage in about 10 per cent of patients If the hemorrhage is massive a fatal issue may ensue in a matter of minutes hours or a day or two deep coma persisting in association with labored respiration attacks of extensor rigidity and finally respiratory arrest and circulatory collapse In these rapidly fatal cases the blood has often dissected intracerebrally and may have reached the ventricular system Death occasionally occurs within 5 to 10 min and ruptured aneurysm must be considered in the differential diagnosis of sudden death

In milder cases consciousness may be regained within a few minutes but a residuum of confusion and amnesia persists for a day or two thereafter accompanied by an excruciating headache and stiff neck However it is not uncommon for drowsiness and confusion to last 7 to 10 days or longer If the hemorrhage is confined to the subarachnoid space there are few or no lateralizing neurologic signs

In most patients there are no warning symptoms whatsoever in some however minor leakage from the aneurysm sometimes precedes devastating rupture by a few days or weeks headache being the chief sign of such an event Aneurysmal rupture usually occurs while the patient is active rather than during sleep and sexual intercourse or other exertion has preceded this event in many instances

Although gross lateralizing signs in the form of hemiplegia hemiparesis or aphasia are absent in the majority of cases they are nonetheless frequently encountered They may result from an intracerebral collection of blood due to the rupture of the aneurysm partly into brain tissue as well as into the subarachnoid space (subarachnoid cerebral hemorrhage) in which case the patient often remains comatose or stuporous When the hemorrhage burrows further and ruptures into the ventricular system under high pressure deep coma and death result (subarachnoid cerebroventricular hemorrhage) Often the neurologic deficit clears up in a matter of days The pathogenesis of these milder more transient focal signs which are not attributable to intracerebral bleeding is not clear vasospasm produced by the presence of subarachnoid blood has without good evidence been invoked as the cause Ischemic necrosis of tissue in the territory of the vessel bearing the aneurysm usually without thrombosis may be found post mortem

Although in most patients the neurologic manifestations do not point to the exact site of the aneurysm in many instances hints as to localiza

tion are provided For example (1) third nerve palsy (ptosis diplopia mydriasis and oculomotor paralysis) usually indicates an aneurysm at the junction of the posterior communicating artery and the internal carotid stem The third nerve lies immediately lateral to this point (2) Transient paresis of one or both of the lower limbs at the onset of the hemorrhage is suggestive of an anterior communicating aneurysm which has interfered with the circulation in the anterior cerebral arteries causing ischemia of the motor areas for the lower extremities (3) Hemiparesis or aphasia points to an aneurysm at the bifurcation of the middle cerebral artery which has critically reduced the circulation in the middle cerebral system (4) Unilateral blindness or amblyopia indicates an aneurysm which lies anteromedially in the circle of Willis (at the origin of the ophthalmic artery at the bifurcation of the internal carotid artery or a large aneurysm of the anterior communicating region) (5) A curious state of retained consciousness with akinetic mutism abulia or adynamia favors an aneurysm of the anterior communicating artery which has caused ischemia of or hemorrhage into one or both of the frontal lobes and the corpus callosum The side on which the aneurysm lies may be indicated by a unilateral preponderance of headache or preretinal hemorrhages by the occurrence of monocular pain or by the lateralization of an intracranial sound at the time of rupture of the aneurysm Sixth nerve palsy unilateral or bilateral results from the presence of subarachnoid blood and raised intracranial pressure and is seldom of localizing value Other neurologic signs which have relatively little localizing value include sucking and grasping reflexes choreoathetosis and extensor rigidity

In summary the clinical sequence of sudden and violent headache collapse brief unconsciousness and confusion combined with an absence of prodromal symptoms or a paucity of lateralizing signs is diagnostic of a ruptured saccular aneurysm (or angioma)

Other clinical data are of assistance in reaching a correct diagnosis A fever with the temperature rising to 102 F is common in the first week Nuchal rigidity is usually present Examination of the fundi not infrequently reveals smooth surfaced sharply outlined collections of blood which cover the retinal vessels—the so-called "preretinal or subhyaloid hemorrhages These are usually a sign of ruptured aneurysm or angioma Bilateral Babinski signs are found in the early days following rupture especially if there is impairment of consciousness The patient may appear to be normally alert yet impairment of memory and confabulation may be present on more careful testing A faint intracranial bruit the mechanism of which is not clear may rarely be heard and may indicate an angioma

Spontaneous intracranial bleeding with normal blood pressure should always suggest ruptured aneurysm ruptured angioma or hemorrhage into a cerebral tumor The escaping blood occasionally enters the subdural space and produces a subdural hematoma evacuation of which may be lifesaving Aneurysmal rupture may complicate pregnancy but pregnancy is not associated with an increased incidence of aneurysmal rupture

Carotid and vertebral angiography using Diodrast or Hypaque will demonstrate the aneurysm in some 70 per cent of patients in which aneurysm seemed to be the correct diagnosis on clinical grounds i e in cases of so-called "spontaneous subarachnoid hemorrhage X rays of the skull are usually negative though in a few patients one or both of the anterior clinoid processes has been eroded by the pressure of an adjacent aneurysm or calcification has occurred in the region of a previous hemorrhage A calcified pineal gland may be shifted because of an intracerebral or subdural clot

The electroencephalogram is of little help in lateralizing the lesion unless a gross neurologic deficit is present in which case the lateralization is probably already evident clinically The abnormality usually consists of slow waves

Laboratory Findings Urinary examination may reveal transient glycosuria and albuminuria and rarely diabetes insipidus Any other urinary abnormalities are due to concomitant renal disease A leukocytosis of 15 000 to 18 000 is common The cerebrospinal fluid is usually extremely bloody with red cell counts reaching to 1 000 000 per cubic millimeter or higher It is unlikely that an aneurysm can rupture entirely into brain tissue without some leakage of blood into the subarachnoid fluid and therefore the diagnosis of ruptured saccular aneurysm must never be made unless blood is present in the spinal fluid (Only expanding saccular aneurysms which compress the optic nerves and chiasm or cranial nerves and intracavernous aneurysms produce symptoms without hemorrhage) Usually deep xanthochromia is found after centrifugation The cerebrospinal fluid is under greatly increased pressure as high as 1 000 mm of fluid (see p 294 regarding traumatic tap) The white blood cells in the spinal fluid are usually present in the same proportion to red blood cells as pertains in the circulating blood but within 48 hr a brisk leukocytosis appears reaching to 2 000 to 3 000 per cubic millimeter in some patients

Course and Prognosis It is estimated by Walton from studies based for the most part on clinically diagnosed cases that approximately 30 per cent of patients die as the result of the first hemorrhage—15 per cent in the first 24 hr 15 per cent in the following 13 days In many of these cases sub

arachnoid cerebral or subarachnoid cerebroventricular hemorrhage has occurred Unlike cases of primary intracerebral hemorrhage recurrence of bleeding is common in saccular aneurysms and rerupture is responsible for death in another 20 per cent of cases in the 6 weeks following the initial ictus with a decreasing incidence of fatal hemorrhages thereafter Recurrence is most common in the second week The threat of recurrence therefore colors all prognostications and unfortunately there appears to be no reliable way of determining in which cases rebleeding will occur If recurrence does not mar recovery the restoration of normal function will depend on the severity of the neurologic change In cases of mild to moderate severity without lateralizing signs full recovery is the rule However one third of the survivors are completely or significantly disabled by paralysis epilepsy mental deterioration or headache Chronic cerebral seizures are an aftermath in about 5 per cent of cases A few patients develop a chronic obstructive or communicating hydrocephalus with persistent headache and confusion or stupor relieved by ventricular drainage Each successive recurrence of bleeding carries with it the same grave prognosis as the initial one and very few patients survive three hemorrhages If they do a disabling neurologic deficit usually remains A succession of subarachnoid hemorrhages five or more always suggests an angioma The cause of the intermittency of bleeding is not understood Patients with the typical clinical picture of spontaneous subarachnoid hemorrhage but in whom the angiogram shows no aneurysm or angioma have a much better prognosis than those in whom the lesion is demonstrated

Treatment General medical management in the acute stage is similar to that described under cerebral thrombosis (p 1583) Any specific measures are based on the assumption that decreasing the arterial blood pressure is the most reasonable way of arresting bleeding and preventing further bleeding Absolute bed rest for 4 to 8 weeks is prescribed with the head of the bed raised some 15 to 20 Straining during bowel movement is forbidden and laxatives or gentle enemas are administered Coughing and all forms of exertion are carefully avoided The patient is fed The duration of the period of bed rest is empirical and not founded on any observations on the formation of scar tissue around aneurysms Sedatives (barbiturates) and analgesics (opiates acetylsalicylic acid) are important in aiding relaxation The use of hypotensive agents has been widely suggested no proof of their efficacy has been presented In the presence of severe hypertension hexamethonium orally or by injection may be cautiously used to lower the blood pressure to 160/100 great care being exercised not to precipitate cerebral infarction Hexamethonium and chlorpromazine are usually not effective in lowering the blood pressure of normotensives confined to bed Chlorpromazine intramuscularly is used to control nausea and vomiting Dilantin or phenobarbital is prescribed routinely to prevent cerebral seizures

The place of repeated drainage of the cerebrospinal fluid by lumbar puncture is still uncertain although several workers have found it makes no difference in the outcome of the illness At present one lumbar puncture is usually carried out for diagnostic purposes and thereafter it is performed only for the relief of intractable headache to detect recurrence of bleeding or to measure the intracranial pressure prior to arteriography or surgery

In maintaining fluid balance intravenous fluids should be used sparingly and in the proper electrolyte combination (a mixture of equal parts of 5 per cent glucose in water and normal saline solution or balanced electrolytes) in order to minimize the danger of aggravating brain swelling Any abnormality of concentration of electrolytes in the blood must be corrected Diabetes insipidus is treated with pitressin Disorders of blood coagulation should be amended Vitamins C and K have been recommended but there is no evidence that they are beneficial The use of body hypothermia for 2 to 5 days in the stage of acute hemorrhage has recently been introduced but cannot yet be evaluated

After resting in bed for 6 weeks the patient is gradually allowed to resume activity and may return to work in 4 months Usually heavy laboring work is forbidden although this advice is not based on recorded experience

Surgical Therapy Surgical treatment has been for the most part directed to the prevention of the recurrence of hemorrhage The procedures are either *extracranial* (ligation of the common carotid in the neck) or *intracranial* (resection of the aneurysm ligation of the neck of the aneurysm wrapping or tamponade of the aneurysmal sac by muscle fascia or arterial graft trapping the aneurysm ligation of the main vessel proximal to aneurysm) Occasionally extracranial and intracranial procedures are combined Because of the high operative mortality if surgery is undertaken early operation has usually been delayed until the patient s condition has stabilized following the first hemorrhage During the waiting period however about 25 per cent of patients will suffer a further hemorrhage and it is in an effort to reach these patients before rebleeding occurs that neurosurgeons are now attempting to operate much earlier than formerly using hypothermic and hypotensive anesthesia Before surgery is undertaken the site size

and form of the aneurysm must be determined by bilateral carotid angiography At the same time the pattern of the anterior half of the circle of Willis is noted as it may influence the choice of operative procedure

OTHER CAUSES OF INTRACRANIAL HEMORRHAGE

1 *Angioma* An angioma or hemangioma consists of a tangle of vessels of varying size forming an abnormal communication between the arterial and venous systems It is a developmental abnormality and not a neoplasm but the constituent vessels enlarge with growth and the passage of time Angiomas vary in size from small blemishes a few millimeters in diameter lying in the cortex to huge masses of tortuous channels comprising an arteriovenous shunt of sufficient magnitude to raise the cardiac output Hypertrophic dilated arterial "feeders" approach the main lesion disappear below the cortex, and break up into a network of thin walled blood vessels which connect directly with draining veins The latter often form huge dilated pulsating channels carrying away arterial blood Angiomas occur in all parts of the brain brain stem and spinal cord but the larger ones are more frequently found in the middle and anterior cerebral territories commonly forming a wedge-shaped lesion extending from the cortex to the ventricular lining The blood vessels forming the tangle interposed between arteries and veins are usually abnormally thin and do not have the normal structure of arteries or veins

This condition predominates in males over females about 2 1 Although the lesion is present from birth, the onset of complaints is most common between the ages of ten and thirty but occasionally is delayed as late as the fifties The chief clinical features are epileptic seizures and cerebral subarachnoid hemorrhage In 50 per cent the first manifestation is a fit in 20 per cent an intracerebral hemorrhage with hemiplegia and in 20 per cent a typical subarachnoid hemorrhage The seizures are usually focal motor in type and may be followed by a temporary postictal paralysis When hemorrhage occurs blood may enter the subarachnoid space almost exclusively producing a picture identical with that of ruptured saccular aneurysm or since the angioma lies within cerebral tissue the bleeding may be partly intracerebral resulting in a deficit such as hemiparesis Nondescript headache is a frequent complaint and occasionally typical migraine is associated but whether it is the result of the angioma or a coincidence is not certain A systolic intracranial bruit heard best over the eye balls is in young adults almost pathognomonic of angioma The eye grounds may reveal a retinal vascular abnormality The blood pressure may be raised or normal—and it is axiomatic that the occurrence of intracranial bleeding with normal blood pressure should lead to the suspicion of an angioma ruptured saccular aneurysm or hemorrhage into a tumor Preretinal hemorrhages may be found after hemorrhage has occurred X ray of the skull occasionally shows crescentic linear calcification in the vicinity of the larger angiomas Pneumoencephalography may show the picture of an expanding lesion combined with cerebral atrophy a combination typical of angioma. Arteriography is necessary to establish the diagnosis with certainty

Most angiomas bleed sooner or later The first hemorrhage may be fatal but most often bleeding stops for some reason and the patient survives Recurrence of the hemorrhage with a fatal outcome is a constant danger In recent years it has been the practice of neurosurgeons to perform a block dissection and removal of suitably located and localized angiomas

2 *Trauma* Although intracranial bleeding due to head trauma does not rightfully fall within the scope of the stroke problem it must be mentioned here because of the great frequency with which it enters into the differential diagnosis especially in stroke cases in which the history is inadequate or in which the patient falls and injures himself at the onset of the stroke *Acute extradural* and *acute subdural hemorrhage* must always be considered in the patient who under unknown circumstances has abruptly developed a neurologic deficit such as hemiparesis or confusion whether the spinal fluid is bloody or not In *chronic subdural hemorrhage* which can occur without known trauma the indefinite picture of drowsiness confusion and mild hemiparesis may be erroneously attributed to a stroke especially in the elderly person These three conditions must be constantly kept in mind since failure to make the correct diagnosis deprives the patient of surgical intervention which is usually most effective There should be no hesitation in placing diagnostic burr holes a relatively minor procedure in all patients in whom subdural hemorrhage cannot be excluded on clinical grounds *Cerebral contusion* and *laceration* may be a cause of subarachnoid hemorrhage and if the patient has fallen and struck his head at the time of the onset of the stroke it may be difficult or impossible to decide if the red blood cells in the cerebrospinal fluid are due to a cerebrovascular stroke or to cerebral contusion Trauma may also be the cause of *acute or delayed intracerebral hemorrhage acute intracerebellar hemorrhage acute brain swelling* and on rare occasions extensive *focal infarction* of undetermined pathogenesis

arachnoid cerebral or subarachnoid cerebroventricular hemorrhage has occurred Unlike cases of primary intracerebral hemorrhage recurrence of bleeding is common in saccular aneurysms and rerupture is responsible for death in another 20 per cent of cases in the 6 weeks following the initial ictus with a decreasing incidence of fatal hemorrhages thereafter Recurrence is most common in the second week The threat of recurrence therefore colors all prognostications and unfortunately there appears to be no reliable way of determining in which cases rebleeding will occur If recurrence does not mar recovery the restoration of normal function will depend on the severity of the neurologic change In cases of mild to moderate severity without lateralizing signs full recovery is the rule However one third of the survivors are completely or significantly disabled by paralysis epilepsy mental deterioration or headache Chronic cerebral seizures are an aftermath in about 5 per cent of cases A few patients develop a chronic obstructive or communicating hydrocephalus with persistent headache and confusion or stupor relieved by ventricular drainage Each successive recurrence of bleeding carries with it the same grave prognosis as the initial one and very few patients survive three hemorrhages If they do a disabling neurologic deficit usually remains A succession of subarachnoid hemorrhages five or more always suggests an angioma The cause of the intermittency of bleeding is not understood Patients with the typical clinical picture of spontaneous subarachnoid hemorrhage but in whom the angiogram shows no aneurysm or angioma have a much better prognosis than those in whom the lesion is demonstrated

Treatment General medical management in the acute stage is similar to that described under cerebral thrombosis (p 1583) Any specific measures are based on the assumption that decreasing the arterial blood pressure is the most reasonable way of arresting bleeding and preventing further bleeding Absolute bed rest for 4 to 8 weeks is prescribed with the head of the bed raised some 15 to 20 Straining during bowel movement is forbidden and laxatives or gentle enemas are administered Coughing and all forms of exertion are carefully avoided The patient is fed The duration of the period of bed rest is empirical and not founded on any observations on the formation of scar tissue around aneurysms Sedatives (barbiturates) and analgesics (opiates acetylsalicylic acid) are important in aiding relaxation The use of hypotensive agents has been widely suggested no proof of their efficacy has been presented In the presence of severe hypertension hexamethonium orally or by injection may be cautiously used to lower the blood pressure to 160/100 great care being exercised not to precipitate cerebral infarction Hexamethonium and chlorpromazine are usually not effective in lowering the blood pressure of normotensives confined to bed Chlorpromazine intramuscularly is used to control nausea and vomiting Dilantin or phenobarbital is prescribed routinely to prevent cerebral seizures

The place of repeated drainage of the cerebrospinal fluid by lumbar puncture is still uncertain although several workers have found it makes no difference in the outcome of the illness At present one lumbar puncture is usually carried out for diagnostic purposes and thereafter it is performed only for the relief of intractable headache to detect recurrence of bleeding or to measure the intracranial pressure prior to arteriography or surgery

In maintaining fluid balance intravenous fluids should be used sparingly and in the proper electrolyte combination (a mixture of equal parts of 5 per cent glucose in water and normal saline solution or balanced electrolytes) in order to minimize the danger of aggravating brain swelling Any abnormality of concentration of electrolytes in the blood must be corrected Diabetes insipidus is treated with pitressin Disorders of blood coagulation should be amended Vitamins C and K have been recommended but there is no evidence that they are beneficial The use of body hypothermia for 2 to 5 days in the stage of acute hemorrhage has recently been introduced but cannot yet be evaluated

Surgical Therapy Surgical treatment has been for the most part directed to the prevention of the recurrence of hemorrhage The procedures are either *extracranial* (ligation of the common carotid in the neck) or *intracranial* (resection of the aneurysm ligation of the neck of the aneurysm wrapping or tamponade of the aneurysmal sac by muscle fascia or arterial graft trapping the aneurysm ligation of the main vessel proximal to aneurysm) *Occasionally extracranial and intracranial* procedures are combined Because of the high operative mortality if surgery is undertaken early operation has usually been delayed until the patient's condition has stabilized following the first hemorrhage During the waiting period however about 25 per cent of patients will suffer a further hemorrhage and it is in an effort to reach these patients before rebleeding occurs that neurosurgeons are now attempting to operate much earlier than formerly using hypothermic and hypotensive anesthesia Before surgery is undertaken the site size

INFLAMMATORY DISEASES OF BRAIN ARTERIES

As shown in the classification there are many inflammatory diseases of the vessels of the brain for the convenience of the reader they are assembled below

Meningovascular syphilis formerly one of the most frequent causes of occlusive vascular disease in patients of all ages has become a rarity since the introduction of penicillin therapy Neurosyphilis is basically a chronic treponemal cerebrospinal meningitis and as in all forms of chronic meningitis the subarachnoid vessels become involved in the inflammatory process This is the reason for calling syphilitic vascular disease of the brain *meningovascular* If the arteritis is active and symptoms of vascular occlusion are of recent origin there are almost invariably signs of meningitis as evidenced by the elevated cerebrospinal fluid protein and cells and its syphilitic nature is revealed by the positive Wassermann reaction Syphilis must still be considered as a diagnostic possibility in all patients who suffer a brain infarct particularly at an early age In the experience of the authors however the usual error is to assume that a stroke is syphilitic when in fact some other arterial disease is the cause If the cerebrospinal fluid is normal or inactive" meaning that it has normal cell and protein values a stroke will nearly always prove to be nonsyphilitic even when the blood Wassermann reaction is positive Formerly syphilis was erroneously assumed to be the cause of cerebral aneurysms or rupture of vessels with intracerebral or meningeal hemorrhage but now the diagnosis is rarely entertained

Tuberculous meningitis fungous meningitis and the subacute forms of bacterial meningitis (influenzal bacillus staphylococcus pneumococcus) may also be accompanied by vascular disorders of occlusive type in either the cerebral arteries or veins Occasionally in tuberculous meningitis a stroke may be the first clinical sign of meningitis more often it develops after the meningeal symptoms are well established The diagnosis of these meningeal diseases is relatively simple for the cerebrospinal fluid contains the essential clues A treatment which suppresses the meningitis also controls the arteritis *Septic embolism* may be a source of arteritis and sometimes of mycotic aneurysm formation The latter may rupture and cause either cerebral or subarachnoid hemorrhage but more often the clinical manifestations are those of arterial occlusion

Typhus schistosomiasis mansoni mucormycosis malaria and *trichinosis* are rare types of infective inflammatory diseases of the arteries and unlike the above are not secondary to meningeal inflammation The cerebrospinal fluid may be normal or abnormal In typhus and other rickettsial diseases capillary and arteriolar changes and perivascular inflammatory cells are found in the brain and presumably they underlie the convulsions acute psychoses and coma which reflect the central nervous system involvement The internal carotid artery may be occluded in diabetic patients during orbital and cavernous sinus infections with mucormycosis In *trichinosis* the sudden onset of convulsions aphasia hemiplegia and coma may either accompany or more often follow the systemic and muscular symptoms The cause of the cerebral symptoms has not been established Parasites have been found in the brain and in one case known to the authors the cerebral lesions were produced by bland emboli arising in the heart and related to a severe myocarditis Malaria of the malignant or falciparum variety is frequently attended by a clinical state known as "cerebral malaria in which convulsions and coma and sometimes focal symptoms appear to be due to blockage of capillaries and precapillaries by masses of parasitized red blood corpuscles

The *arteritides of obscure origin* include disseminated lupus erythematosus polyarteritis nodosa rheumatic arteritis granulomatous arteritis giant cell arteritis and cranial (temporal) arteritis In systemic lupus erythematosus delirium confusional states convulsions hemiplegia and aphasia and brain stem or cerebellar syndromes may be traced to occlusion of small arteries either by thrombosis or in those cases with Libman Sacks endocarditis by embolism Intracerebral hemorrhage and hypertensive encephalopathy often terminate the illness if renal hypertension has developed

Rheumatic arteritis is still a highly debatable subject Pathologic studies have not provided convincing evidence of a primary arteritis In many of the reported cases infarction which has been the usual parenchymal brain lesion was due to embolism from a rheumatic endocarditis However the close relationship of lupus erythematosus in which there is an arterial lesion and rheumatic fever offers a plausible basis of a primary inflammation of cerebral vessels

Polyarteritis nodosa frequently involves the small blood vessels in the peripheral nerves giving rise to a clinical picture of a multiple asymmetric or symmetric sensorimotor *polyneuropathy* and cerebral vessels usually escape If hypertension becomes severe as it often does brain hemorrhage or hypertensive encephalopathy may occur More recently a granulomatous form of polyarteritis nodosa has been delineated in which the neurologic syndrome has been more encephalitic than vascular with headache ataxia confusion convulsions hemiparesis etc In these latter cases a moderate increase in white blood cells and total protein of the cerebrospinal fluid provides further evidence

3 Several *hemorrhagic hematologic disorders* may at some stage be complicated by hemorrhage into the brain The most frequent of these are leukemia aplastic anemia and thrombopenic purpura As a rule this complication signals a fatal issue Any part of the brain may be involved and not infrequently the lesions are multiple Usually there is already evidence of abnormal bleeding elsewhere (skin mucous membranes kidney) by the time cerebral hemorrhage occurs Intracranial bleeding is a rare complication of anticoagulant therapy

4 On infrequent occasions bleeding within an area of *hemorrhagic* infarction reaches major proportions forming an intracerebral hematoma and the cerebrospinal fluid becomes bloody

5 Brain stem hemorrhages secondary to temporal lobe herniation are extremely common but never present as a cerebrovascular stroke

6 *Hemorrhage into primary and secondary brain tumors* is not rare and when it is the first manifestation of the neoplasm the correct diagnosis may be extremely obscure Chorionepithelioma melanotic carcinoma renal cell carcinoma bronchogenic carcinoma pituitary adenoma glioblastoma multiforme and medulloblastoma may present themselves in this way Careful inquiry will usually disclose the fact that signs of a neurologic disorder compatible with intracranial tumor growth have preceded the onset of hemorrhage Examination directly and by x ray may reveal evidence of intracranial tumor or of secondary tumor deposits in other organs A chest film will frequently reveal evidence of metastatic or primary neoplasm and should be performed in all cases of obscure intracerebral hemorrhage

7 *Septic embolism* may lead to massive fatal intracranial bleeding via the production of a *mycotic aneurysm* Any part of the circulatory tree may be involved but usually the aneurysm lies at a branching or forking of a small vessel (about 0 5 mm in diameter) within the subarachnoid space

8 *Hypertensive encephalopathy* may in its most advanced stage result in intracerebral hemorrhages which can vary in size from the massive type down to petechiae

9 *Idiopathic brain purpura* or hemorrhagic encephalitis consists of multiple petechial hemorrhages scattered throughout the white matter of the brain The picture is that of a diffuse cerebral disease There is never blood in the spinal fluid and the condition should never be confused with a typical stroke

10 *Inflammatory* disease of arteries and veins—more specifically polyarteritis nodosa and lupus erythematosus—may give rise to medium sized hemorrhages especially if renal hypertension develops However because of their relatively small size they do not clinically resemble primary intracerebral hemorrhage

11 *Hemorrhages of undetermined origin* Although this is the final category it is nonetheless important since both clinically and pathologically hemorrhages are found in which the blood pressure is normal and neither an aneurysm nor angioma can be demonstrated In some post mortem cases a careful microscopic search discloses a small angioma in the cerebral tissue at one side of the hemorrhage and on this basis it is suspected that in other cases too an overlooked angioma may have been the cause of the extravasation of blood Primary intraventricular hemorrhage a rare event is at times due to angioma or neoplasm of the choroid plexus which may not have been seen by the prosector

HYPERTENSIVE ENCEPHALOPATHY

This term refers to an acute syndrome in which severe hypertension is associated with headache nausea vomiting convulsions confusion stupor and coma Focal or lateralizing neurologic signs either transitory or lasting are rare and always suggest some other form of vascular disease (hemorrhage embolism atherosclerotic thrombosis) By the time the neurologic manifestations appear the hypertension has usually reached the malignant stage with retinal hemorrhages exudates papilledema (formerly called *uremic retinopathy* now known as *hypertensive retinopathy* grade IV) and evidence of renal and cardiac disease The cerebrospinal fluid pressure and the protein values are both elevated in many but not all of the cases the latter sometimes over 100 mg per cent The hypertension may be essential or due to chronic renal disease acute glomerulonephritis eclampsia pheochromocytoma Cushing s syndrome or ACTH toxicity Lowering of the blood pressure with hypotensive drugs may reverse the picture in a few days or sooner If the hypertension cannot be controlled the patient usually dies within a few days weeks or months Neuropathologic examination may reveal a rather normal looking brain but usually one or more gross changes can be demonstrated including cerebral swelling large and small hemorrhages and petechial hemorrhages Frequent microscopic findings are clusters of glial cells necrosis of arterioles and minute cerebral infarcts

The term *hypertensive encephalopathy* should be reserved for the above syndrome and not used to refer to chronic recurrent headaches dizziness epileptic seizures recurrent transient ischemic attacks or small strokes which often occur in association with high blood pressure For further discussion see p 1363

INFLAMMATORY DISEASES OF BRAIN ARTERIES

As shown in the classification there are many inflammatory diseases of the vessels of the brain for the convenience of the reader they are assembled below

Meningovascular syphilis formerly one of the most frequent causes of occlusive vascular disease in patients of all ages has become a rarity since the introduction of penicillin therapy Neurosyphilis is basically a chronic treponemal cerebrospinal meningitis and as in all forms of chronic meningitis the subarachnoid vessels become involved in the inflammatory process This is the reason for calling syphilitic vascular disease of the brain *meningovascular* If the arteritis is active and symptoms of vascular occlusion are of recent origin there are almost invariably signs of meningitis as evidenced by the elevated cerebrospinal fluid protein and cells and its syphilitic nature is revealed by the positive Wassermann reaction Syphilis must still be considered as a diagnostic possibility in all patients who suffer a brain infarct particularly at an early age In the experience of the authors however the usual error is to assume that a stroke is syphilitic when in fact some other arterial disease is the cause If the cerebrospinal fluid is normal or "inactive" meaning that it has normal cell and protein values a stroke will nearly always prove to be nonsyphilitic even when the blood Wassermann reaction is positive Formerly syphilis was erroneously assumed to be the cause of cerebral aneurysms or rupture of vessels with intracerebral or meningeal hemorrhage but now the diagnosis is rarely entertained

Tuberculous meningitis fungous meningitis and the subacute forms of bacterial meningitis (influenzal bacillus staphylococcus pneumococcus) may also be accompanied by vascular disorders of occlusive type in either the cerebral arteries or veins Occasionally in tuberculous meningitis a stroke may be the first clinical sign of meningitis more often it develops after the meningeal symptoms are well established The diagnosis of these meningeal diseases is relatively simple for the cerebrospinal fluid contains the essential clues A treatment which suppresses the meningitis also controls the arteritis *Septic embolism* may be a source of arteritis and sometimes of mycotic aneurysm formation The latter may rupture and cause either cerebral or subarachnoid hemorrhage but more often the clinical manifestations are those of arterial occlusion

Typhus schistosomiasis mansoni mucormycosis malaria and *trichinosis* are rare types of infective inflammatory diseases of the arteries and unlike the above are not secondary to meningeal inflammation The cerebrospinal fluid may be normal or abnormal In typhus and other rickettsial diseases capillary and arteriolar changes and perivascular inflammatory cells are found in the brain and presumably they underlie the convulsions acute psychoses and coma which reflect the central nervous system involvement The internal carotid artery may be occluded in diabetic patients during orbital and cavernous sinus infections with mucormycosis In *trichinosis* the sudden onset of convulsions aphasia hemiplegia and coma may either accompany or more often follow the systemic and muscular symptoms The cause of the cerebral symptoms has not been established Parasites have been found in the brain and in one case known to the authors the cerebral lesions were produced by bland emboli arising in the heart and related to a severe myocarditis Malaria of the malignant or falciparum variety is frequently attended by a clinical state known as "cerebral malaria" in which convulsions and coma and sometimes focal symptoms appear to be due to blockage of capillaries and precapillaries by masses of parasitized red blood corpuscles

The *arteritides of obscure origin* include disseminated lupus erythematosus polyarteritis nodosa rheumatic arteritis granulomatous arteritis giant-cell arteritis and cranial (temporal) arteritis In systemic lupus erythematosus delirium confusional states convulsions hemiplegia and aphasia and brain stem or cerebellar syndromes may be traced to occlusion of small arteries either by thrombosis or in those cases with Libman Sacks endocarditis by embolism Intracerebral hemorrhage and hypertensive encephalopathy often terminate the illness if renal hypertension has developed

Rheumatic arteritis is still a highly debatable subject Pathologic studies have not provided convincing evidence of a primary arteritis In many of the reported cases infarction which has been the usual parenchymal brain lesion was due to embolism from a rheumatic endocarditis However the close relationship of lupus erythematosus in which there is an arterial lesion and rheumatic fever offers a plausible basis of a primary inflammation of cerebral vessels

Polyarteritis nodosa frequently involves the small blood vessels in the peripheral nerves giving rise to a clinical picture of a multiple asymmetric or symmetric sensorimotor *polyneuropathy* and cerebral vessels usually escape If hypertension becomes severe as it often does brain hemorrhage or hypertensive encephalopathy may occur More recently a granulomatous form of polyarteritis nodosa has been delineated in which the neurologic syndrome has been more "encephalitic" than "vascular" with headache ataxia confusion convulsions hemiparesis etc In these latter cases a moderate increase in white blood cells and total protein of the cerebrospinal fluid provides further evidence

that the illness is not an ordinary type of vascular disease

Cranial arteritis (temporal arteritis) is an uncommon affliction of elderly persons in which the branches of the external carotid arteries particularly the temporal ones are the seat of a subacute granulomatous inflammation with an exudate of lymphocytes monocytes neutrophilic leukocytes and giant cells Usually the most severely affected parts of the artery become thrombosed This aspect of the disease is distressingly painful The inflammatory nature of the illness is betrayed by fever slight leukocytosis increased sedimentation rate and sometimes anemia Occlusion of the ophthalmic arteries may result in blindness in one or both eyes in over 50 per cent of patients and occasionally an ophthalmoplegia due to involvement of ocular nerves occurs Although strokes have been observed in these patients significant inflammatory involvement of intracranial arteries has rarely been demonstrated An arteritis of the aorta and its major branches including carotid subclavian coronary and femoral arteries has been found in a few fatal cases in which a post mortem examination was made Meticorten and ACTH bring striking subjective relief but whether or not they prevent blindness has not been clearly decided See p 1708 for further discussion

A closely related disease called *giant cell arteritis* may affect younger people in it all the branches of the aorta including the common carotid arteries may become occluded This disease was described long ago in Japan (Takayasu) and in Norway (Harbitz) The vascular pathology is not well defined but chronic inflammation with destruction of all coats of the vessel infiltrates of lymphocytes plasma cells and mononuclear leukocytes the presence of giant cells and thrombosis comprise the lesion The cause of the disease is unknown There is no information concerning therapy See Chap 229 and p 1570

Thromboangiitis obliterans (Winiwarter Buerger disease) of cerebral vessels is not included in the classification Despite the large amount of literature on the subject the pathology is so dubious that it does not merit further exposition All the patients that the authors have studied proved to have had either atherosclerosis of the carotid or cerebral arteries with stasis thrombosis" of more distal cerebral branches Buerger s disease of the legs has an equally uncertain status

THE DIAGNOSIS OF CEREBROVASCULAR DISEASE

There are two separate aspects to the problem of differential diagnosis (1) vascular disease must be distinguished from other neurologic illnesses (2) the different kinds of vascular diseases must be separated from one another In the following pages many of the important points discussed in the body of the chapter will be recapitulated

1 *Differentiation of vascular disease from other neurologic illnesses* It has already been stated that the diagnosis of a vascular lesion rests solely on the recognition of the cerebrovascular stroke and that without evidence of this the diagnosis must always be in doubt Three criteria have already been emphasized as having practical utility in the identification of the stroke (*a*) the temporal profile of the clinical syndrome (*b*) evidence of focal brain disease and (*c*) the clinical setting The clinical profile can usually be ascertained by a clear history of premonitory phenomena the mode of onset and the evolution of the neurologic disturbance taken in relationship to the medical status at the time of examination If these data are lacking the course may still be determined by extending the period of observation over days or weeks thus resorting to the clinical rule that the physician s best diagnostic tool is the second and third examination An inadequate history is probably the most frequent cause of diagnostic errors

As stated above the neurologic deficit in a cerebrovascular stroke nearly always develops suddenly and in the later part of its course if death does not occur stabilization and some degree of recovery take place There are few neurologic illnesses whose temporal profile mimics that of cerebrovascular disorders Tumor infection inflammation degeneration and nutritional disorders are not likely to manifest themselves precipitously In trauma of course a sudden insult occurs but usually injury is readily recognizable as the cause Multiple sclerosis and other demyelinative diseases often have abrupt episodes of exacerbation but are seldom as sudden in onset as vascular diseases and for the most part they occur in a different age group and clinical setting

Many thrombotic strokes are preceded by transient ischemic episodes which if they are nonconvulsive in nature are almost diagnostic of vascular disease Their differentiation from cerebral seizures attacks of Ménière s syndrome and paralytic migraine was discussed in the description of intermittent cerebral ischemia A stroke developing over a period of several days usually progresses in a stepwise fashion rather than evolving smoothly increments of additional deficit are added serially from time to time A slow gradual downhill course over a period of days or weeks indicates that the lesion is probably not vascular but rather a tumor abscess granuloma or subdural hematoma

The focal neurologic deficit in cerebrovascular disease is usually a hemipl[illegible] of face arm and

leg associated with hemianesthesia or hemihypesthesia homonymous hemianopia aphasia agnosia etc but it is obvious from the above descriptions that there are many other manifestations which must be recognized as the product of vascular disease However many nonvascular neurologic diseases (tumor abscess etc) also produce focal neurologic deficits which are not strikingly different from those resulting from vascular disease and the diagnosis usually cannot rest solely on this aspect of the clinical picture Nonetheless certain combinations of neurologic signs which conform to a neurovascular pattern e g the lateral medullary syndrome are seen almost exclusively in occlusive vascular disease

The presence of blood in the cerebrospinal fluid always points to a cerebrovascular lesion providing that trauma and a bloody tap can be excluded It must be repeated that *headache* is not infrequent as a prodromal manifestation or an actual accompaniment of the development of a thrombotic stroke *Cerebral seizures* almost never the premonitory manifestation of a stroke can occur early in the course of intracranial bleeding but are extremely uncommon early in the course of infarction (the first 2 days) *Brief unconsciousness* (5 to 10 min) is rare in stroke cases being seen only in ruptured aneurysm The presence of certain neurologic disturbances which occur rarely in cerebrovascular disease e g diabetes insipidus bitemporal hemianopia parkinsonism generalized myoclonus and isolated cranial nerve palsies may be of help in ruling out the diagnosis

Finally it is recommended that the diagnosis of cerebrovascular disease always be made on positive data Diagnosis by exclusion is too precarious

A few conditions are so often confused with the cerebrovascular diseases that they merit further consideration When a history of trauma is absent the headache drowsiness and mild hemiparesis accompanying a *subdural hematoma* may all too easily be ascribed to a slight stroke and the patient may fail to receive immediate surgical therapy In classic subdural hematoma the symptoms and signs will usually develop gradually over a period of days or weeks The degree of obtundation and confusion will often be disproportionately great in comparison with the focal neurologic deficit which tends to be indefinite and variable Short of arteriography pneumoencephalography or operation a subdural hematoma may be indicated by finding in the x ray of the skull a fracture line or a shift of the pineal gland The cerebrospinal fluid may be blood tinged or xanthochromic where the type of stroke under suspicion would not be expected to show this The electroencephalogram occasionally is strikingly silent over a subdural hematoma and this may be of help in diagnosis If the patient has fallen and injured his head at the onset of the stroke it may be impossible to rule out a complicating subdural hematoma without performing diagnostic burr holes

The reverse diagnostic error of mistaking a stroke for a subdural hematoma is also often made Here it is helpful to remember that patients with subdural hematoma rarely exhibit a complete hemiplegia a monoplegia a hemianesthesia a homonymous hemianopia or a well-developed aphasia If these focal signs are present and particularly if they developed suddenly the diagnosis of subdural hematoma is far less likely than stroke

A *brain tumor* especially a rapidly growing glioblastoma multiforme which may produce a severe hemiplegia within a week or two is often mistaken for a stroke Secondary carcinoma also may quickly lead to a marked neurologic deficit However in both conditions a detailed history will show that the course was gradual and if the symptoms progressed in saltatory fashion it was usually punctuated by seizures A routine chest film will be of great help in detecting a primary or secondary source of cancer in the lung An increased blood sedimentation rate may suggest that a systemic disease process is at work Rarely a *brain abscess* occurs without any known primary antecedent focus of infection and may not be considered in the diagnosis especially if the patient is elderly

Senile dementia with its progressive loss of memory and enfeeblement of the intellect is often ascribed on insufficient grounds to multiple small strokes possibly in silent areas of the brain If vascular lesions are responsible evidence of them will be divulged by the history (sudden onset episodic development) and by examination (a focal neurologic deficit motor sensory aphasia etc) The commonest cause of mental deterioration in the elderly patient is Alzheimer s disease or related degenerative processes and in the absence of focal neurologic signs it is unwarranted to assign cerebral vascular disease—in particular small strokes in silent areas—as the cause of this syndrome Cerebral arteriosclerosis is another term used too loosely as an explanation for such mental changes the inference being that multiple areas of focal ischemia irreparably damaged the nervous system producing loss of memory but no other focal neurologic signs If cerebral arteriosclerosis (atherosclerosis) is actually responsible there should be evidence of it in the brain (strokes) heart (myocardial infarction angina pectoris) or legs (intermittent claudication)

Chronic cerebral seizures occur as the result of the stroke (*poststroke seizures*) in some 20 per cent of cases When the seizures are infrequent or not properly observed or when they leave behind a temporary increase in the neurologic deficit

(Todd s paralysis) the diagnosis of another stroke may be made in error

Fear anxiety and *depression* in patients who have had one small stroke may lead to additional symptoms such as alterations in the paresthesias headache or disequilibrium which suggest to the patient and his physician that further vascular lesions have occurred or threaten

Miscellaneous conditions which occasionally lead to the suspicion of a stroke are Bell s palsy Stokes Adams attacks diabetic ophthalmoplegia acute ulnar radial or peroneal palsy embolism to a limb and cranial arteritis associated with blindness

Strokes may be wrongly diagnosed as other neurologic illnesses This happens under a variety of circumstances but often it is because of inability to obtain a detailed history with the result that the mode of development of the focal neurologic deficit remains in question Unfortunately some of these patients who are subjected to pneumoencephalography for the diagnosis of these other conditions sometimes develop widespread brain infarction because of the fall in the systemic blood pressure during the procedure In the lateral medullary syndrome *dysphagia* may be the outstanding feature if the syndrome is not kept in mind the patient may be suspected of harboring an esophageal neoplasm and a fruitless surgical investigation may be entered into *Headache* at times occurs as the prodrome of an oncoming thrombotic stroke unless this is appreciated a diagnosis of migraine may be reached The diagnosis of such an illness occurring *for the first* time in a middle aged patient should be made only with great reluctance In the elderly patient *vertiginous attacks* due to vascular disease of the brain stem may be diagnosed as labyrinthine disease or Meniere s syndrome (see Chap 29) Stokes Adams syncopal attacks or paroxysmal tachycardia may be erroneously diagnosed when dizzy spells or brief lapses or intermittent loss of equilibrium are the principal manifestation of cerebrovascular disease A detailed account of the attack will usually serve to circumvent this error A strikingly focal monoplegia of cerebral origin involving only the hand or producing only a foot drop is not infrequently misdiagnosed as a peripheral lesion

The differentiation of vascular disease from other neurologic illnesses in the presence of coma offers special problems If the patient is comatose when first seen and an adequate history is not available cerebrovascular lesions will have to be differentiated from all the other causes of coma described on p 314 In most cases some history will be at hand to assist in the series of diagnostic deductions described below The cerebrovascular causes of coma are as follows hypertensive intracerebral hemorrhage ruptured saccular or mycotic aneurysm ruptured angioma basilar artery embolism or thrombosis acute hypertensive encephalopathy with brain edema extensive infarction including most of one cerebral hemisphere (due to occlusion of a major arterial trunk) bilateral occlusion of the internal carotid arteries bilateral cerebral embolism multiple septic emboli and widespread cerebral ischemia due to systemic hypotension (shock due to gastrointestinal bleeding myocardial infarction ruptured aneurysm Stokes Adams attacks syncope) Nearly all these forms of cerebrovascular coma are accompanied by focal or lateralizing neurologic signs or changes in the cerebrospinal fluid which aid in separating them from toxic and metabolic abnormalities (see Chap 33)

2 *Differentiation of thrombosis embolism and hemorrhage* It is difficult to set up hard and fast rules but usually it is possible to distinguish the three conditions at the bedside

The most important criteria of *atherosclerotic thrombosis* are (1) a history of prodromal transient ischemic attacks (2) an intermittent or stepwise evolution of the neurologic deficit often with recovery or improvement between worsenings rather than a steady progression (3) relative preservation of consciousness unless the upper part of the basilar territory is infarcted (4) clear cerebrospinal fluid (except in meningovascular syphilis intracranial arteritis and occasionally an idiopathic pleocytosis with bland infarction) (5) the occurrence of rapid improvement at times (6) onset during sleep or shortly after arising while eating or during a period of hypotension (7) certain constellations of symptoms and signs e g the lateral medullary syndrome (8) evidence of atherosclerosis elsewhere especially in the coronary and peripheral vessels and aorta (9) the presence of disorders usually associated with atherosclerosis (hypertension diabetes mellitus and xanthomatosis) (10) headache of moderate severity (may be prodromal warning or may accompany stroke) (11) contralateral cranial bruit (may indicate carotid occlusion of thrombotic type) (12) occlusion of the internal carotid artery in the neck whether spontaneous" or posttraumatic (usually of thrombotic origin)

Cerebral embolism is characterized by (1) sudden onset of the clinical picture within a period of a few seconds or minutes (2) the absence of prodromal transient ischemic attacks (rarely one or two transitory episodes occur in embolism) (3) a source of embolus usually in the heart—atrial fibrillation or other arrhythmia myocardial infarction subacute bacterial endocarditis mitral stenosis valvulotomy marantic endocarditis associated with carcinoma (4) evidence of recent embolism in other organs i e spleen kidney extremities gastrointestinal tract or lungs (5) evidence of recent involvement of several regions of the brain

in different cerebrovascular territories (6) clear cerebrospinal fluid except in those cases in which extensive bleeding occurs in an area of hemorrhagic infarction (most often even in hemorrhagic infarction the cerebrospinal fluid is clear or at most *faintly xanthochromic*) (7) rapid improvement (many embolic strokes produce persistent deficits but it is not uncommon for an extensive focal cerebral disorder to reverse itself in minutes or hours) (8) relative preservation of consciousness in the presence of extensive neurologic deficit unless the upper part of the basilar territory is affected or massive brain swelling *has occurred with temporal* lobe tentorial herniation (9) occurrence at an age when atherosclerosis is usually not a factor and in the absence of hypertension arteritis or infection (10) a *headache* of moderate severity which not infrequently accompanies cerebral embolism

Other causes of cerebral infarction The *diagnosis of arteritis* as a cause of infarction is justifiable only in the following circumstances (1) evidence of an arteritis elsewhere (2) in young individuals who manifest neither hypertension nor signs of cardiovascular disease and (3) in individuals with a meningeal infection which could affect the meningeal vessels (syphilis tuberculosis) *Venous thrombosis with infarction* should be especially considered when focal neurologic signs develop after an operation or in the period following parturition in the course of meningeal infection ear or sinus suppuration diseases which result in cachexia and sickle cell disease or polycythemia

In *hypertensive cerebral hemorrhage* the diagnosis rests on (1) history of the gradual development of a deficit over a period of 10 to 15 min or more (sometimes the onset appears to have been *abrupt*) *(2) absence of any prodromal phenomena* (3) presence of hypertension (4) grossly bloody spinal fluid under elevated pressure due to rupture of the hemorrhage into the ventricles (this is not invariable—there are cases in which the hemorrhage does not extend to the ventricular system to reach the cerebrospinal fluid accurate diagnosis *is difficult in these patients*) (5) *deepening coma* and general deterioration of the neurologic condition (in general if there is an extensive paralysis the patient is likely to be deeply or moderately stuporous if not comatose a cerebrovascular stroke which leaves the patient alert and the mind relatively clear proves in nearly all instances to be due to an infarct) (6) *severe headache often but* not invariably present (7) a lateral displacement of the pineal gland (evidence of a hemorrhage rather than of an infarct provided that massive brain swelling can be excluded) (8) the neck being supple or only mildly rigid on forward flexion (9) persistence of the neurologic deficit (an evanescent stroke is never due to a hemorrhage since extravasated blood is removed very slowly from the brain tissues) (10) onset during waking hours rather than in sleep

The *chief clinical features of ruptured saccular aneurysm* are (1) sudden onset of severe headache with or without a transient disturbance of consciousness (in the most severe cases coma persists and the patient dies within a few hours) (2) stiff neck on forward bending Kernig and Brudzinski signs (3) grossly bloody spinal fluid under increased pressure (rupture of a saccular aneurysm without subarachnoid hemorrhage rarely if ever *occurs except in the case of aneurysms within the* cavernous sinus grossly bloody cerebrospinal fluid in the presence of a third nerve palsy indicates a ruptured aneurysm at the origin of the posterior communicating artery from the internal carotid artery) (4) absence of hypertension in many cases (5) onset during exertion sexual intercourse etc (6) usually an absence of prodromal warnings although there may be a history of one or more premonitory leaks associated with transient headache (7) preretinal (subhyaloid) hemorrhages (these suggest ruptured aneurysm or angioma although they can occur in massive intracerebral hemorrhage) (8) a relative absence of focal neurologic signs Saccular aneurysm is likely to produce a diffuse subarachnoid hemorrhage without causing significant damage to the cerebral hemispheres If the cerebrospinal fluid is *bloody and the patient* retains mental clarity or is only mildly confused aneurysm is the diagnosis of choice If the aneurysm bleeds into the brain tissue (subarachnoid-cerebral hemorrhage) or into the ventricular system also (subarachnoid cerebroventricular hemorrhage) focal neurologic signs and coma ensue as in intra*cerebral hemorrhage Cerebral infarction associated* with ruptured aneurysm not an uncommon event is another cause for a focal neurologic deficit In the latter circumstance often the patient will remain alert

Other conditions which may exist include coarctation of the aorta and polycystic disease of the *kidneys*

Intracranial hemorrhage from a nonaneurysmal vascular malformation is a tenable diagnosis under the following circumstances (1) repeated subarachnoid hemorrhages (sometimes more than five) (2) stroke in a young patient with bloody cerebrospinal fluid in the absence of hypertension (3) *antecedent periodic headaches* or epilepsy often with transient postictal paralysis (4) presence of a cranial bruit (5) calcification in the region of the lesion in x ray of the skull

For a discussion of the other causes of intracranial hemorrhage (hemorrhage into primary and secondary brain tumors hematologic disorders *hemorrhage into hemorrhagic* infarction septic

embolism etc) see Chap 145 and pp 1201 1209 The existence of acute leukemia aplastic anemia thrombopenic purpura or cirrhosis of the liver favors the diagnosis of intracranial hemorrhage due to hemorrhagic disease especially if other hemorrhagic manifestations are present

LABORATORY METHODS OF DIAGNOSIS

A number of special laboratory tests are of value in the diagnosis of cerebrovascular disease but none of them can approach in general usefulness a careful history and physical examination The importance of lumbar puncture has already been mentioned If a fine needle is used No 20 and jugular veins are not compressed there is probably little danger in doing a spinal tap in most cases Nevertheless the procedure should not be routine in every case a decision should be reached at the time of the first examination as to the necessity of the procedure and as to the most appropriate time If cerebellar or temporal lobe herniation is threatening the lumbar puncture may contribute to a fatal issue and should be deferred unless absolutely necessary This is especially so in brain hemorrhage massive cerebral infarction cerebellar infarction and hypertensive encephalopathy In primary subarachnoid hemorrhage the lumbar puncture although necessary for diagnosis should not be repeated except to investigate the possibility of further hemorrhage or in order to alleviate severe headache It is not advisable to attempt to remove the blood in the cerebrospinal fluid by repeated punctures

Many cases of apoplexy should have x rays of the skull en route to a hospital bed especially if there is any suspicion of trauma The finding of unexpected fractures a displaced pineal gland or calcification in an aneurysm or vascular malformation will be helpful in diagnosis X ray of the chest is useful as part of the cardiac examination and sometimes will disclose a pulmonary neoplasm or a dissecting aortic aneurysm

Blood cell counts also provide useful information A high hematocrit suggests that polycythemia is a factor a severe anemia and greatly increased sedimentation rate might provide a clue to the existence of subacute bacterial endocarditis and should lead to a blood culture Leukemia and thrombopenia of course must be diagnosed from the blood examination In aneurysmal ruptures there may be a transient albuminuria and hyperglycemia with glycosuria Hypertensive hemorrhage too can cause hyperglycemia Serologic tests for syphilis should be done on the blood and spinal

electrocardiogram should be obtained in all cerebral infarction Occasionally it will presence of a recent silent myocardial

P

infarct or provide correlative evidence of hypertension An electroencephalogram is abnormal in most major strokes and is a useful means of following the course of the illness However its utility in the diagnosis of cerebrovascular diseases has yet to be determined

Carotid arteriography is indispensable in the diagnosis of aneurysms and vascular malformations Some 75 to 80 per cent of such lesions within the territory of the carotid arteries are revealed by this method It carries some risk always and the authors have not in the past favored its use in cerebral infarction except in a few cases of suspected occlusion of the internal carotid artery With recent interest in vascular surgery of the carotid system *arteriography* will have to be used with increasing frequency Retinal arterial pressure measurements have also been of help in detecting occlusion of the internal carotid artery

CONCLUSION

Of all the forms of neurologic disease those described in this chapter are of the greatest importance to the practicing physician The assiduous application of clinical method and laboratory test will permit diagnosis of the type of cerebrovascular disease with approximately 75 per cent accuracy enabling the physician to use sensible therapeutic measures in many of the cases Future developments it is hoped will improve both the accuracy of diagnosis and the effectiveness of therapy

255 TRAUMATIC DISEASES OF THE BRAIN AND SPINAL CORD

Karl Erik Astrom
Henri vander Eecken and
Raymond D Adams

TRAUMATIC DISEASES OF THE BRAIN

Head injury which is the basis of some of the most frequent and serious neurologic disorders in these times of high velocity transport and mechanization in industry poses many problems to the practicing physician To deal with them effectively demands a knowledge of the clinical manifestations as well as a sound grasp of fundamental physiologic mechanisms The physician must stand prepared at all times for he may at any moment be summoned to render aid or to assess the clinical status of a person who has suffered an injury of the head or spine The present chapter undertakes to review the salient facts concerning these injuries of the nervous system and to outline an approach to these problems that has been useful to the authors

Physiologic and Pathologic Considerations

The very language with which certain types of head injury are discussed divulges a number of misconceptions that have been inherited from previous generations of physicians Words have crept into medical vocabulary and have often been retained long after the ideas for which they stood have been refuted—clear evidence of the disadvantage of prematurely adopting explanatory rather than descriptive terms The word *concussion* for example implies the violent shaking and agitation of an organ or the functional impairment which results therefrom Yet despite numerous experiments intended to demonstrate these physical changes within nerve cells (vibration effects formation of intracellular vacuoles etc) no confirmation of their existence has been possible Similarly the word *contusion* meaning a bruising or crushing without interruption of physical continuity is applied rather indiscriminately to a variety of clinical states some of which could not depend on a pathologic change of this type e g minor contusion state or syndrome"—an expression introduced by Wilfred Trotter who was himself most critical of words that embalm a fallacious theory

In all attempts to analyze the mechanism of brain damage in head injury one fact stands preeminent—that there must be the sudden application of a physical force of considerable magnitude to the head Unless the head is struck the brain suffers no injury—except in the rare and somewhat controversial cases of crush injury to the chest or explosive injury with raised intrapulmonary pressure in which petechial hemorrhages are said to have been found in the brain A second fact also susceptible of easy verification is that the size of the area on the skull over which the force is exerted is of importance High velocity missiles destroy a small part of the skull and penetrate the cranial cavity without significant displacement of the head or brain and heavy crushing injuries which result from the skull being compressed between two converging objects may crush the brain In these two circumstances it is interesting to note that the patient may suffer severe and often fatal injury without immediate loss of consciousness Hemorrhage destruction of brain tissue and if the patient survives for a time meningitis or abscess are the principal pathologic changes created by injuries of this type They offer little difficulty to understanding

The common civilian injury is one in which a rapidly moving blunt object strikes the head or the head is flung against a hard surface Injuries of this type often termed *blunt head injuries* are remarkable in two respects (1) they almost always induce at least a temporary loss of consciousness (2) even though the skull is not penetrated and fragments of bone are not driven into its cavity the brain may suffer gross damage i e contusion laceration hemorrhage swelling herniation etc Clinicians as well as experimental physiologists have sought a theory which would bring into plausible form all gross neuropathologic changes the skull fracture and the transient paralysis of nervous function (concussion) or prolonged coma so often observed in fatal cases It may be said that a comprehensive theory acceptable to all workers in this field has not been developed as yet

The relation of skull fracture to injury of the cerebral tissues has been viewed in changing perspective through the entire history of this subject In earliest times fractures dominated the thinking of the medical profession and cerebral lesions were regarded as secondary Some of the best articles on the location of fractures and their relationship to anatomic peculiarities of the cranial bones were written in the eighteenth and nineteenth centuries Later it became known that the skull although rigid is still flexible enough to yield to a severe blow without fracture Therefore the presence of a fracture although a rough measure of the violence to which the brain has been exposed is not an infallible index and even in fatal head injury autopsy may reveal an intact skull in 20 to 30 per

cent of cases Also many patients suffer skull fracture without serious disorder of cerebral function

The modern trend is to be interested more in the presence or absence of brain injury than in the fracture of the skull itself Nevertheless fractures cannot be dismissed without a few comments for they assume importance in indicating the site and possible severity of brain damage in providing an explanation for cranial nerve palsies and in affording potential pathways for the ingress of bacteria and air or the egress of cerebrospinal fluid

The existence of a basal skull fracture may be indicated by *signs of cranial nerve damage* Cranial nerves which are particularly liable to injury are the olfactory optic oculomotor first and second branches of the trigeminal the facial and the auditory Anosmia and an apparent loss of taste (actually a loss of aromatic flavors elementary tastes—salt sweet bitter sour—being retained) are frequent sequelae of head injury especially of falls on the back of the head In the *majority* of cases the anosmia is permanent or the patient may have some perversion of smell (parosmia) The anosmia may be unilateral and not noticed by the patient The mechanism of these disturbances is believed to be displacement of the brain and tearing of the olfactory nerve filaments A fracture in or near the sella may tear the stalk of the pituitary gland with resulting diabetes insipidus A fracture of sphenoid bone may lacerate the optic nerve with complete blindness from the beginning The pupil is dilated and unreactive to a direct light stimulus but still takes part in the consensual reflex The optic disk becomes pale i e atrophic after an interval of several weeks Partial injuries may result in a troublesome blurring of vision Injury to the eighth cranial nerve with petrosal fractures causes loss of hearing and/or dizziness immediately after injury The deafness due to nerve injury must be distinguished from that caused by rupture of the eardrum or the presence of blood in the middle ear and the vertigo from posttraumatic giddiness In oculomotor nerve injury there is a divergent squint with loss of internal and vertical movement of the eye and a fixed dilated pupil Diplopia only on looking down suggests trochlear nerve affection Direct injury of the facial nerve by a basal fracture may be present immediately after the injury or may be delayed coming on after several days This delayed form is usually transitory and its mechanism is not known It may be misinterpreted as an important progression of the traumatic intracranial lesion Injury to the ophthalmic or maxillary divi*sions of the trigeminal nerve may* be the result either of a basal fracture across the middle cranial fossa or of a direct extracranial injury to the branches of these nerves Numbness and paresthesias over the area of skin supplied by the nerve or a troublesome neuralgia are the sequelae of these injuries

If the skin is lacerated over the skull fracture and the underlying meninges are torn or if the fracture *passes through the posterior wall of a nasal sinus* bacteria or air may enter the cranial cavity (meningitis abscess aerocele) Cerebrospinal fluid may also leak into the sinus and present as a watery discharge from the nose (cerebrospinal fluid rhinorrhea) Persistence of the rhinorrhea or the occurrence of episodes of recurrent meningitis (headache convulsions fever and stiff neck with pleocytosis *and sometimes bacteria) are often indications for* a repair of the torn dura mater over the fissure Depressed fractures are of significance only if the underlying dura is lacerated by spicules of bone or the brain is compressed

Much has been written about the mechanism of coma in closed or blunt head injury Two facts concerning this condition stand out clearly (1) it *bears no relationship to skull fracture* (2) the optimal conditions for its production are those in which there is some change in the momentum of the head i e movement is suddenly imparted to it by a blow or its movement is suddenly arrested Striking the stationary head of an experimental animal will cause a loss of brain stem reflexes only if the head was free to move not if it is clamped in one position (Denny Brown and Russell) This finding alone would stand in refutation of such theories of concussion as a wave of high intracranial pressure due to the indentation of the skull or a subsequent wave of negative pressure (Kahn Ward and Clark) cerebral anemia (Trotter) or a general vibration or agitation transmitted via the skull The speed of acceleration or deceleration of the head necessary for this concussive effect must exceed 28 ft per sec The initial action of the blunt injury of this type is to excite the nervous system (the stars that one sees with a minor injury the gasp of the animal) and this is followed by transient paralysis of cerebral function i e abolition of consciousness suppression of reflexes arrest of respiration etc The means whereby the latter effects are produced is not known The old studies of Fischer and Alquie show that in most head injuries there is displacement of the brain within the skull The brain being suspended in a water jacket of cerebrospinal fluid tends not to follow movements of the cranium but to lag because of its own inertia The superior parts of the cerebral hemispheres are free to move more than the lower parts which are *attached to the relatively fixed* brain stem There is the possibility then of stretch or torsion on midbrain and subthalamic structures and indeed temporary paralysis of the reticular activating mechanism which is located in these parts of the brain has recently been demonstrated

This could account for both the unconsciousness and suppression of reflexes and also the electroencephalographic changes (relative electrical silence followed by slow waves) It would appear however that the cerebrum itself does not escape damage for Meyer and Denny Brown have found evidence of an electrical injury potential and reduction in oxygen uptake in the cerebral cortex The changes *whatever and wherever they may be are for the* most part transitory and would be expected to have no visible structural basis Pathologic changes such as have been described in several published accounts of experimental concussion are difficult to evaluate The report of diffuse degeneration of the cerebral white matter in rabbits and monkeys which were repeatedly struck on the head (Jakob) the observation of petechial hemorrhages in the cervical cord and medulla in the cat dog and monkey (Denny Brown and Russell) and the demonstration of chromatolysis of large nerve cells in the brain stem of concussed animals (Windle et al) have not been verified It is unlikely that any of them could be the pathologic basis of the concussive state

In fatal cases of severe head injury where this concussive injury *must also have existed the brain* is almost invariably bruised or lacerated and often there is hemorrhage either meningeal or intracerebral *The observation of these gross pathologic* findings had led to the widely prevalent view that head injuries are largely matters of bruises and hemorrhages and of urgent operations That this can hardly be the case is suggested by the fact that some patients survive head injuries almost as severe as the fatal ones and yet make an excellent recovery At autopsy years later old contusions (*plaques jaunes*) and hemorrhages of approximately the same distribution and extent as those observed in some of the immediately fatal cases are found One can only conclude therefore that most of the immediate symptomatology of severe head injury both *general and localized depends on invisible* and highly reversible change in the brain probably of the same nature as that which underlies concussion Nevertheless these bruises lacerations hemorrhages and localized swellings of tissues cannot be disregarded because they are probably responsible for many of the fatalities that occur 12 to 72 or more hours after the injury Of these lesions the most important is the surface bruising of the brain beneath the point of impact (coup injury) and the more extensive lacerations and contusions on the opposite side of the brain (contrecoup injuries) The inertia of the brain which causes it to be flung *against the side of the skull that was* struck and to be pulled away from the contralateral side has been invoked to explain these coup contrecoup contusions This theory has been further elaborated by Holburn who points out that the brain is roughly spherical and that all movements of the head describe an arc with its axis at the *point of attachment of skull to spine Sudden* changes in the momentum of the head therefore induce a swirling motion to the brain which may *then suffer injury against all rough bony prominences* (wings of sphenoid bones petrous parts of temporal bones rough surfaces of orbital and frontal bones) The lacerations and hemorrhages are based on a similar mechanism the latter being due merely to the tearing of larger vessels Also extensive infarction of the brain may occur when cerebral arteries are compressed between a herniating mass of brain and the dura e g the posterior cerebral artery in temporal lobe herniations An important fact from the standpoint of the clinician is that these contusions hemorrhages and extensive necrotic lesions whatever their mechanism may be may occur without a penetrating head injury and under these circumstances they and their clinical effects are engrafted upon the traumatic paralysis of cerebral function which is called *concussion* They are in a sense epiphenomena which nonetheless may unfavorably tip the balance of life and *death The most compelling evidence of the correctness* of this view is that head injury may end fatally without any visible structural change in the nervous system However *in most fatal cases a* significant degree of bruising edema hemorrhage and herniation is also present

Clinical Manifestations of Head Injury

The physician upon being called to see a patient who has had a head injury will generally find him in one of three clinical conditions each as Trotter Symonds and Rowbotham have pointed out must be dealt with differently It is usually possible to place the patient in one of the following three categories by determining the degree of unconsciousness at intervals of time after the accident *and by assessing the mental* and general neurologic status when the patient is first seen

Patients Who Are Conscious or Are Rapidly Regaining Mental Clarity When *First Seen (Minor* Head Injury) The typical example is a patient who was rendered unconscious by a knock on the head and then regained his senses within seconds minutes or hours Roughly two degrees of disturbance of consciousness may have occurred First there is the patient who was never unconscious at all He was observed to have struck his head and was stunned or saw stars By all criteria his head injury was insignificant when judged in terms of *life and death* and severe brain damage though in exceptional cases there is always the possibility of skull fracture or epidural or subdural hematoma Nevertheless a troublesome *group of symptoms* may have developed at once or within a few days The

patient may begin to complain of headache dizziness loss of confidence in himself inability to concentrate nervousness poor sleep fatigue and depression The headache is of a pressing aching type and is characteristically worsened by any physical and mental effort stooping and excitement No clue is provided as to the mechanism of these symptoms The possibility that these symptoms represent a traumatic or *compensation neurosis* is suggested because of the purely subjective nature of the symptoms and lack of abnormal neurologic signs and the absence of change in cerebrospinal fluid or alteration of the EEG In recent years a better appreciation of the constancy of this clinical syndrome has favored the view first put forward by Wilfred Trotter that they are the direct physical effects of injury incorrectly designated by him *minor cerebral contusion* state The severity of these symptoms is not clearly related to the severity of the head injury Their persistence constitutes a most vexatious therapeutic problem

If consciousness was temporarily abolished the patient is said to have suffered a *concussion* defined by Trotter as an essentially transient state due to head injury which is instantaneous in onset manifests widespread symptoms of a purely paralytic kind does not as such comprise any evidence of structural cerebral injury and is always followed by amnesia for the actual moment of the impact The patient if observed immediately after the injury shows a complete paralysis of nervous function In a few instances death has occurred at this time from respiratory arrest or cardiac arrhythmia and no lesion was found at post mortem examination However the usual sequela is for the pulse and respiration (if they were depressed or arrested) to return at once and for muscle tone reflexes voluntary movement and mental clarity to be regained within a few minutes Only an amnesia for the accident and the events that immediately preceded (retrograde amnesia) and followed it (anterograde amnesia) will remain Thereafter the patient may suffer the same headaches giddiness and nervousness described above

These relatively trivial head injuries may be the source of a number of other puzzling features (1) *Delayed traumatic collapse* following an accident a few patients after walking about and seeming to be mentally normal will turn pale and fall unconscious for a few minutes This is a vasomotor syncopal attack and is probably related to injury pain and emotional upset Rarely do they exhibit any focal or lateralizing neurologic signs The suggestion that this represents medullary edema is hardly tenable (2) *Immediate traumatic paraplegia* with falls on top of the head which may injure the motor areas for the lower extremities both legs may become temporarily weak and numb sometimes with bilateral Babinski signs and sphincteric incontinence Concussion of the cervical segments of the spinal cord is another possible mechanism of this paraplegia (3) *Immediate hemiplegia* or *monoplegia* these conditions may develop immediately after a minor injury with or without blood in the cerebrospinal fluid and are commonly attributed to a relatively circumscript injury with *minimal concussion and a direct contusion or laceration* of the underlying brain (cerebrospinal fluid is sanguineous) (4) *Immediate traumatic epilepsy* a series of focal seizures may occur with a minor bruise of the cortex and may be followed by a postepileptic paralysis of short duration (5) *Delayed hemiplegia or monoplegia in interval paralysis* in cases of minor or major injury usually signifies an epidural hemorrhage a subdural hemorrhage or hygroma arterial thrombosis spreading venous thrombosis or intracerebral hemorrhage (6) *Acute drowsiness confusion* and *headache* or *coma* due presumably to localized and generalized traumatic brain edema children who have had concussion are especially liable to headache drowsiness and vomiting which may have its onset some hours after the *injury* In these children infusions and clyses of water and 5 per cent glucose are particularly dangerous such treatment may prove fatal owing to a water intoxication and severe brain swelling Apparently an excessive output of antidiuretic hormone and water retention occur under these circumstances

Patients Who Are and Have Been Unconscious Since the Time of the Accident (Major Head Injury) ***The Clinical State*** In this group which includes the patients with the more severe head injuries the outlook is obviously less favorable and one is concerned at first for their life However within this group there is still a wide variation in the severity of the traumatic brain disease A certain number of patients die at once or within a few minutes and it may be assumed that the direct injury to the brain or some other organ was incompatible with life Other patients in this group recover consciousness rapidly after several hours but a few remain deeply comatose for days or even weeks The mortality rate in those who reach a hospital in coma is approximately 20 per cent and most of them die within the first 12 to 24 hr Of those alive after 24 hr the mortality is 7 to 8 per cent and after 48 hr the figure falls to 1 per cent

In the patient whose prognosis is favorable the coma is less deep (stupor semicoma or confusion —see Chap 33) For a time he may be restless and difficult to control The reflexes are normal as are pulse blood pressure and respiration He is able to swallow and may or may not speak There are no obvious neurologic signs In contrast those patients whose illness will end fatally may be moribund

from the beginning Their coma is profound The limbs may be flaccid and without reflexes The corneal and pharyngeal (gag) reflexes are absent The pupils are small and unreactive to light or dilated and fixed or unequal The ocular axes are divergent or askew The jaw sags the tongue falls back in the throat saliva drools from the mouth and swallowing is obviously lost There may be surgical shock at first for a brief period with the usual findings of pale and moist skin weak and rapid pulse subnormal temperature and a blood pressure that is difficult to obtain Within a few hours however the temperature usually rises and this may continue until death The breathing may be stertorous and later feeble and irregular The state of consciousness and the temperature chart provide information of great value in appraising the status of the patient An ascending pulse rate possibly interspersed by short periods in which there is a bounding slow pulse and rising temperature or a combination of fast pulse and subnormal temperature are signs of a grave prognosis

In the group of patients whose outlook is less bleak deep coma soon gives way to semicoma The blood pressure stabilizes and the temperature and pulse having risen to 101 to 102 F and 100 to 110 respectively remain at these levels Muscular tone is regained in the limbs and the tendon reflexes are present This is a critical period for a sudden rise in temperature cyanosis and increasing respiratory difficulty may result in a fatal issue Once the patient regains consciousness sufficiently to respond to a spoken command the physician no longer needs to be concerned about survival and may begin to think about the possibility of focal brain damage and prospects for recovery There is still a substantial risk in the first 2 or 3 weeks however from pneumonia meningitis or epidural and subdural hemorrhage which may intervene and impair the chances of survival It is often said that death during the first 12 hr is the result of the direct injury of the brain that which occurs later is usually the result of some complication of cranial trauma (intracerebral or subarachnoid hemorrhage herniation of the temporal lobe localized or generalized edema epidural or subdural hemorrhage meningitis pneumonia)

The course of clinical events in those who survive the first 24 to 48 hr is much like that in patients with type I injury except that it is likely to be more prolonged As coma lessens the patient opens his eyes he may pause in his restless activity and seem to listen to what is said He reacts briskly to painful stimuli applied to the face passive manipulations of the head and pinching the inner surface of the arms or legs Moaning and groaning are the first vocal activities to return their absence in patients who are beginning to respond always suggests aphasia Restlessness irritability and hyperactivity may assume such proportions that the patient must be restrained For example he may resist all attempts to help him struggle against restraints yell talk incessantly and without sense strike at everyone near the bed etc This state sometimes called *traumatic delirium* may last hours or days but eventually is replaced by a more quiet confusional state Then the patient speaks unless aphasic and is variably able to engage in conversation His thinking processes are slow and inefficient and his thoughts are likely to be incoherent Often he cannot understand the purposes of his splints bandages catheters etc and will remove them even when asked repeatedly not to do so Movements and reactions to stimuli are more or less automatic and if conversation is possible it is repetitious and often incoherent Also memory is obviously faulty As confusion lessens there may be a brief period when mental function is nearly normal yet later there will be little or no memory for what transpired From a close study of this clinical sequence it is obvious that the capacity to form retain and reproduce new experiences is one of the best tests of the mental status Not until the patient reaches the stage of continuous anterograde memory will he regard himself as fully normal In looking back upon this period the patient can recall only a few events and has the impression that he was unconscious all this time Retrograde amnesia for the accident and for the events which preceded it which often extends over a period of minutes hours or even days is another invariable accompaniment of severe head injury This period of retrograde memory defect shortens as convalescence proceeds

Focal and lateralizing neurologic symptoms and signs as would be anticipated will be observed with notable frequency in this group of patients These abnormalities are presumably related to hemorrhage and contusion and in as much as they are usually engrafted on a severe concussive injury they become manifest as consciousness is regained Local injury to the brain without a disturbance of consciousness occurs exceptionally and then more often with the penetration of the skull by missiles or a direct or glancing blow by a relatively small object (golf ball stone) sometimes with depression fractures Of the focal symptoms hemiparesis is probably the most frequent The weakness of arm and leg may be evident even during coma by the hypotonia the less frequent movement of the limbs inequality of tendon reflexes and a more persistent Babinski sign on one side Complete hemiplegia is rarely observed Hemihypesthesia although occasionally found is less common possibly because sensory tests are difficult to interpret until mental clarity is regained Homonymous hemi

patient may begin to complain of headache dizziness loss of confidence in himself inability to concentrate nervousness poor sleep fatigue and depression The headache is of a pressing aching type and is characteristically worsened by any physical and mental effort stooping and excitement No clue is provided as to the mechanism of these symptoms The possibility that these symptoms represent a traumatic or compensation neurosis is suggested because of the purely subjective nature of the symptoms and lack of abnormal neurologic signs and the absence of change in cerebrospinal fluid or alteration of the EEG In recent years a better appreciation of the constancy of this clinical syndrome has favored the view first put forward by Wilfred Trotter that they are the direct physical effects of injury incorrectly designated by him *minor cerebral contusion* state The severity of these symptoms is not clearly related to the severity of the head injury Their persistence constitutes a most vexatious therapeutic problem

If consciousness was temporarily abolished the patient is said to have suffered a *concussion* defined by Trotter as an essentially transient state due to head injury which is instantaneous in onset manifests widespread symptoms of a purely paralytic kind does not as such comprise any evidence of structural cerebral injury and is always followed by amnesia for the actual moment of the impact The patient if observed immediately after the injury shows a complete paralysis of nervous function In a few instances death has occurred at this time from respiratory arrest or cardiac arrhythmia and no lesion was found at post mortem examination However the usual sequela is for the pulse and respiration (if they were depressed or arrested) to return at once and for muscle tone reflexes voluntary movement and mental clarity to be regained within a few minutes Only an amnesia for the accident and the events that immediately preceded (retrograde amnesia) and followed it (anterograde amnesia) will remain Thereafter the patient may suffer the same headaches giddiness and nervousness described above

These relatively trivial head injuries may be the source of a number of other puzzling features (1) *Delayed traumatic collapse* following an accident a few patients after walking about and seeming to be mentally normal will turn pale and fall unconscious for a few minutes This is a vasomotor syncopal attack and is probably related to injury pain and emotional upset Rarely do they exhibit any focal or lateralizing neurologic signs The suggestion that this represents medullary edema is hardly tenable (2) *Immediate traumatic paraplegia* with falls on top of the head which may injure the motor areas for the lower extremities both legs may become temporarily weak and numb sometimes with bilateral Babinski signs and sphincteric incontinence Concussion of the cervical segments of the spinal cord is another possible mechanism of this paraplegia (3) *Immediate hemiplegia* or *monoplegia* these conditions may develop immediately after a minor injury with or without blood in the cerebrospinal fluid and are commonly attributed to a relatively circumscript injury with minimal concussion and a direct contusion or laceration of the underlying brain (cerebrospinal fluid is sanguineous) (4) *Immediate traumatic epilepsy* a series of focal seizures may occur with a minor bruise of the cortex and may be followed by a post epileptic paralysis of short duration (5) *Delayed hemiplegia* or *monoplegia* an interval" paralysis in cases of minor or major injury usually signifies an epidural hemorrhage a subdural hemorrhage or hygroma arterial thrombosis spreading venous thrombosis or intracerebral hemorrhage (6) *Acute drowsiness confusion* and *headache* or *coma* due presumably to localized and generalized traumatic brain edema children who have had concussion are especially liable to headache drowsiness and vomiting which may have its onset some hours after the injury In these children infusions and clyses of water and 5 per cent glucose are particularly dangerous such treatment may prove fatal owing to a water intoxication and severe brain swelling Apparently an excessive output of antidiuretic hormone and water retention occur under these circumstances

Patients Who Are and Have Been Unconscious Since the Time of the Accident (Major Head Injury) *The Clinical State* In this group which includes the patients with the more severe head injuries the outlook is obviously less favorable and one is concerned at first for their life However within this group there is *still a wide variation in the severity of the traumatic brain disease* A certain number of patients die at once or within a few minutes and it may be assumed that the direct injury to the brain or some other organ was incompatible with life Other patients in this group recover consciousness rapidly after several hours but a few remain deeply comatose for days or even weeks The mortality rate in those who reach a hospital in coma is approximately 20 per cent and most of them die within the first 12 to 24 hr Of those alive after 24 hr the mortality is 7 to 8 per cent and after 48 hr the figure falls to 1 per cent

In the patient whose prognosis is favorable the coma is less deep (stupor semicoma or confusion —see Chap 33) For a time he may be restless and difficult to control The reflexes are normal as are pulse blood pressure and respiration He is able to swallow and may or may not speak There are no obvious neurologic signs In contrast those patients whose illness will end fatally may be moribund

The surgical procedure is placement of several burr holes (a single one may miss the clot) drainage identification of the bleeding vessel and ligation The operative results are excellent except in the cases with extensive fractures and laceration of the dural venous sinuses in which instance the epidural hematoma may be bilateral rather than unilateral as it ordinarily is If coma bilateral Babinski signs spasticity or decerebrate rigidity supervene before operation the prognosis for life becomes poor This usually means that a temporal lobe herniation and crushing of the midbrain have already occurred

Acute and Chronic Subdural Hematoma The problems created by the acute and the chronic subdural hematoma are so different that they must be discussed separately In *acute subdural hematomas* which may be unilateral or bilateral the latent interval is usually longer than in epidural hemorrhage—many days or 1 to 2 weeks Headaches drowsiness sometimes agitation slowness in thinking and confusion which progressively worsen are the most frequent symptoms Focal or lateralizing signs (hemiplegia) are late and tend to be less prominent than the disturbance of consciousness Frequently the acute subdural hematoma is combined with cerebral contusion and laceration so that the clinical effects of these several lesions are difficult to distinguish and there are some patients in whom it is impossible before operation to state whether the surface clot is epidural or subdural in location The treatment is bilateral temporal burr holes and thus is also one of the most certain diagnostic procedures If the clot that is found is too small to explain the symptoms the surgeon usually proceeds to do a right subtemporal decompression

In chronic subdural hematoma mentioned in the differential diagnoses in Chaps 36 254 and 256 the traumatic etiology is less clear The head injury especially in the elderly person may be trivial (striking the head against a branch of a tree or on the mantel of a fireplace during a faint etc) or it may have been forgotten completely A period of weeks then follows when headaches (not invariable) giddiness slowness in thinking confusion exaggeration of certain personality traits and rarely a seizure or two are the main symptoms The initial impression may be that the patient has a brain tumor a drug intoxication or a depressive senile or other psychosis As with acute subdural hematoma the disturbance of consciousness (drowsiness inattentiveness incoherence of thought stupor or coma) is more prominent than focal or lateralizing signs The latter usually consist of hemiparesis and rarely of an aphasic disturbance Hemianesthesia and homonymous hemianopia are seldom observed probably because the anatomic structures subserving these functions are deep and not easily compressed (in the case of hemianopia) and sensory changes are likely to be overlooked in a stuporous confused patient Hemiplegia i e complete paralysis of one arm and leg is usually indicative of an intracerebral lesion rather than of a compressive surface lesion Another important feature of the hemiparesis is that it may be contralateral or ipsilateral depending on whether or not herniation of the temporal lobe through the notch of the tentorium into the posterior fossa and compression of the contralateral cerebral peduncle are present if they are present pyramidal signs are then ipsilateral to the clot or bilateral As the condition progresses the patient becomes comatose but often with striking fluctuations of awareness The ipsilateral pupil dilates (Hutchinson s pupillary sign) owing it is believed to direct pressure of the herniating temporal lobe upon the oculomotor nerve The dilated pupil and a ptotic eyelid are more reliable indicators of the side of the hematoma than the hemiparesis though they too can be misleading in certain cases Convulsions are usually seen only in alcoholics or cases with a contusion and cannot be regarded as a cardinal sign of subdural hematoma even though they are not infrequent Roentgenograms of the skull are usually negative except for a shift of a calcified pineal to one side or an occasional unexpected fracture line The EEG is usually bilaterally abnormal sometimes with reduced voltage or electrical silence over the subdural hematoma or high voltage slow waves over the same and opposite sides because of the damping effects of the clot and displacement of the brain The anterior and middle cerebral arteries are seen to be displaced in an arteriogram The cerebrospinal fluid may be clear bloody or xanthochromic depending on the presence or absence of recent or old contusion and subarachnoid hemorrhage and the pressure may be elevated normal or subnormal Of all these diagnostic procedures direct burr hole exploration is the most reliable

The acute rapidly evolving subdural hematomas are due to tearing of bridging veins and direct compression of the brain by an expanding clot of fresh blood Unlike the epidural arterial hemorrhage which is progressive the bleeding is usually arrested by the rising intracranial pressure The chronic subdural hematoma is believed to cause symptoms by becoming encysted by fibrous membranes (pseudomembranes) which grow from the dura In its encysted state as red corpuscles hemolyze and blood proteins disintegrate the osmotic pressure rises and fluids enter the hematoma with the result that the hematoma enlarges and the compressive effects increase Severe cerebral compression and displacement with temporal lobe–tentorial herniation are the usual causes of death

anopia is not at all infrequent and may present early as an inattentiveness to visual stimuli on one side Aphasia usually of mixed type has been noted in a number of the cases A series of focal seizures may occur within a few days of the time of injury and as said before are probably due to cortical contusion They usually cease after a few days and do not necessarily signify that epilepsy is to be a sequel to the trauma Diabetes insipidus disturbances of sleep (reversal of rhythm somnolence later narcolepsy) diplopia heteronymous visual field defects gastrointestinal hemorrhage amenorrhea and impotence in the male indicate damage to the hypothalamus and walls of the third ventricle Midbrain lesions are evidenced by ocular palsies protracted coma (weeks months or years) decerebrate rigidity crossed ocular limb paralyses bilateral Babinski signs and later dysarthria, ataxia of limbs on one side and sensory disturbances

Laboratory Findings In this group of patients with severe head injury there is a high incidence of skull fracture The cerebrospinal fluid is usually sanguineous (red blood cells usually 100 000 per cubic millimeter or less) and under elevated pressure (between 200 and 300 mm) in the majority of patients The prognosis is distinctly less good in those *with more than 100 000 red cells per cubic* millimeter and pressures in excess of 300 mm Nevertheless death may occur in patients who have no skull fracture a subnormal intracranial pressure and relatively clear cerebrospinal fluid The EEG regularly shows focal and diffuse abnormalities

Neuropathologic Findings In patients who die during the first few hours or days after a severe head injury hemorrhage and necrosis of tissue will frequently be observed In 50 consecutive autopsies summarized in Rowbotham s excellent monograph only two showed no macroscopic change Lacerations of cerebral cortex (28 per cent) surface contusions (48 per cent) subarachnoid hemorrhage (72 per cent) acute subdural hemorrhage (16 per cent) extradural hemorrhage (20 per cent) were the usual findings As a rule several of these pathologic changes were found in the same case Skull fractures were discovered in 72 per cent With such striking gross lesions there is a great temptation to assume that they account for the deep coma and the other general neurologic findings though as already pointed out this assumption may be erroneous The basis of at least part of the general symptoms (coma stupor delirium confusion) is usually the initial concussion itself which is nearly always of greater magnitude than that seen in cases of the first group Recovery from hemiplegia, aphasia etc must indicate some reversible process near the contusions and hemorrhages (localized cerebral edema?) This use of the term *concussion* to refer to a prolonged instead of transient (usually defined as less than 5 min) traumatically induced loss of consciousness has been criticized by many physicians Nevertheless there is no reason to believe that the same forces which cause a brief cerebral disorder could not when acting more forcibly cause a more protracted one This is not to deny of course that expanding clots cerebral herniations midbrain hemorrhages and high intracranial pressure so frequent in this group are responsible for the most prolonged states of coma

Patients Who Are Unconscious When First Seen but Who Are Said to Have Been Conscious after the Accident (Presence of Lucid Interval) This group of patients is smaller than the other two but is of great importance because it includes many who are in urgent need of surgical treatment The initial coma may have been brief or there may have been none at all in which instance one may conclude that there was neither concussion nor contusion The following conditions must be considered in every case of this type

Acute Epidural Hemorrhage This condition is due as a rule to a temporal or parietal fracture with laceration of the middle meningeal artery and vein Less often there is a tear in a dural venous sinus The injury even when it fractures the skull *may not have produced coma A typical example is* a child who has fallen from a bicycle or a swing or has suffered a hard blow to the head in a fight and was only momentarily unconscious A few hours or a day or two later (the interval may be as long as several days or a week especially with venous bleeding) he develops headache of increasing severity vomiting drowsiness confusion seizures which may be one sided hemiparesis with slightly increased tendon reflexes and Babinski sign As coma develops the hemiparesis with Babinski sign may give way to flaccid or spastic limbs and Babinski signs bilaterally There may be aphasia Respirations become deeper and stertorous then shallow and irregular and finally stop The pulse is often slow (below 60) and bounding with a concomitant rise in systolic blood pressure The pupil may dilate on the side of the hematoma The cerebrospinal fluid is usually under increased pressure though normal and subnormal pressures do not exclude the possibility of an epidural hematoma The fluid may be clear or sanguineous depending on whether or not there is an associated contusion laceration or subarachnoid hemorrhage Death which is almost invariable if the clot is not removed surgically comes at the end of a comatose period rarely if ever in a conscious patient and is due to respiratory arrest The visualization of a fracture line across the groove for the middle meningeal artery and a knowledge of the side of the head struck (the clot is usually on that side) are of aid in diagnosis and of lateralization of the lesion

The surgical procedure is placement of several burr holes (a single one may miss the clot) drainage identification of the bleeding vessel and ligation The operative results are excellent except in the cases with extensive fractures and laceration of the dural venous sinuses in which instance the epidural hematoma may be bilateral rather than unilateral as it ordinarily is If coma bilateral Babinski signs spasticity or decerebrate rigidity supervene before operation the prognosis for life becomes poor This usually means that a temporal lobe herniation and crushing of the midbrain have already occurred

Acute and Chronic Subdural Hematoma The problems created by the acute and the chronic subdural hematoma are so different that they must be discussed separately In *acute subdural hematomas* which may be unilateral or bilateral the latent interval is usually longer than in epidural hemorrhage—many days or 1 to 2 weeks Headaches drowsiness sometimes agitation slowness in thinking and confusion which progressively worsen are the most frequent symptoms Focal or lateralizing signs (hemiplegia) are late and tend to be less prominent than the disturbance of consciousness Frequently the acute subdural hematoma is combined with cerebral contusion and laceration so that the clinical effects of these several lesions are difficult to distinguish and there are some patients in whom it is impossible before operation to state whether the surface clot is epidural or subdural in location The treatment is bilateral temporal burr holes and this is also one of the most certain diagnostic procedures If the clot that is found is too small to explain the symptoms the surgeon usually proceeds to do a right subtemporal decompression

In chronic subdural hematoma mentioned in the differential diagnoses in Chaps 36 254 and 256 the traumatic etiology is less clear The head injury especially in the elderly person may be trivial (striking the head against a branch of a tree or on the mantel of a fireplace during a faint etc) or it may have been forgotten completely A period of weeks then follows when headaches (not invariable) giddiness slowness in thinking confusion exaggeration of certain personality traits and rarely a seizure or two are the main symptoms The initial impression may be that the patient has a brain tumor a drug intoxication or a depressive senile or other psychosis As with acute subdural hematoma the disturbance of consciousness (drowsiness inattentiveness incoherence of thought stupor or coma) is more prominent than focal or lateralizing signs The latter usually consist of hemiparesis and rarely of an aphasic disturbance Hemianesthesia and homonymous hemianopia are seldom observed probably because the anatomic structures subserving these functions are deep and not easily compressed (in the case of hemianopia) and sensory changes are likely to be overlooked in a stuporous confused patient Hemiplegia i e complete paralysis of one arm and leg is usually indicative of an intracerebral lesion rather than of a compressive surface lesion Another important feature of the hemiparesis is that it may be contralateral or ipsilateral depending on whether or not herniation of the temporal lobe through the notch of the tentorium into the posterior fossa and compression of the contralateral cerebral peduncle are present if they are present pyramidal signs are then ipsilateral to the clot or bilateral As the condition progresses the patient becomes comatose but often with striking fluctuations of awareness The ipsilateral pupil dilates (Hutchinson s pupillary sign) owing it is believed to direct pressure of the herniating temporal lobe upon the oculomotor nerve The dilated pupil and a ptotic eyelid are more reliable indicators of the side of the hematoma than the hemiparesis though they too can be misleading in certain cases Convulsions are usually seen only in alcoholics or cases with a contusion and cannot be regarded as a cardinal sign of subdural hematoma even though they are not infrequent Roentgenograms of the skull are usually negative except for a shift of a calcified pineal to one side or an occasional unexpected fracture line The EEG is usually bilaterally abnormal sometimes with reduced voltage or electrical silence over the subdural hematoma or high voltage slow waves over the same and opposite sides because of the damping effects of the clot and displacement of the brain The anterior and middle cerebral arteries are seen to be displaced in an arteriogram The cerebrospinal fluid may be clear bloody or xanthochromic depending on the presence or absence of recent or old contusion and subarachnoid hemorrhage and the pressure may be elevated normal or subnormal Of all these diagnostic procedures direct burr hole exploration is the most reliable

The acute rapidly evolving subdural hematomas are due to tearing of bridging veins and direct compression of the brain by an expanding clot of fresh blood Unlike the epidural arterial hemorrhage which is progressive the bleeding is usually arrested by the rising intracranial pressure The chronic subdural hematoma is believed to cause symptoms by becoming encysted by fibrous membranes (pseudomembranes) which grow from the dura In its encysted state as red corpuscles hemolyze and blood proteins disintegrate the osmotic pressure rises and fluids enter the hematoma with the result that the hematoma enlarges and the compressive effects increase Severe cerebral compression and displacement with temporal lobe–tentorial herniation are the usual causes of death

Laboratory Findings In this group of patients with severe head injury there is a high incidence of skull fracture The cerebrospinal fluid is usually sanguineous (red blood cells usually 100 000 per cubic millimeter or less) and under elevated pressure (between 200 and 300 mm) in the majority of patients The prognosis is distinctly less good in those with more than 100 000 red cells per cubic millimeter and pressures in excess of 300 mm Nevertheless death may occur in patients who have no skull fracture a subnormal intracranial pressure and relatively clear cerebrospinal fluid The EEG regularly shows focal and diffuse abnormalities

Neuropathologic Findings In patients who die during the first few hours or days after a severe head injury hemorrhage and necrosis of tissue will frequently be observed In 50 consecutive autopsies summarized in Rowbotham s excellent monograph only two showed no macroscopic change Lacerations of cerebral cortex (28 per cent) surface contusions (48 per cent) subarachnoid hemorrhage (72 per cent) acute subdural hemorrhage (16 per cent) extradural hemorrhage (20 per cent) were the usual findings As a rule several of these pathologic changes were found in the same case Skull fractures were discovered in 72 per cent With such striking gross lesions there is a great temptation to assume that they account for the deep coma and the other general neurologic findings though as already pointed out this assumption may be erroneous The basis of at least part of the general symptoms (coma stupor delirium confusion) is usually the initial concussion itself which is nearly always of greater magnitude than that seen in cases of the first group Recovery from hemiplegia aphasia etc must indicate some reversible process near the contusions and hemorrhages (localized cerebral edema?) This use of the term *concussion* to refer to a prolonged instead of transient (usually defined as less than 5 min) traumatically induced loss of consciousness has been criticized by many physicians Nevertheless there is no reason to believe that the same forces which cause a brief cerebral disorder could not when acting more forcibly cause a more protracted one This is not to deny of course that expanding clots cerebral herniations midbrain hemorrhages and high intracranial pressure so frequent in this group are responsible for the most prolonged states of coma

Patients Who Are Unconscious When First Seen but Who Are Said to Have Been Conscious after the Accident (Presence of Lucid Interval) This group of patients is smaller than the other two but is of great importance because it includes many who are in urgent need of surgical treatment The initial coma may have been brief or there may have been none at all in which instance one may conclude that there was neither concussion nor contusion The following conditions must be considered in every case of this type

Acute Epidural Hemorrhage This condition is due as a rule to a temporal or parietal fracture with laceration of the middle meningeal artery and vein Less often there is a tear in a dural venous sinus The injury even when it fractures the skull may not have produced coma A typical example is a child who has fallen from a bicycle or a swing or has suffered a hard blow to the head in a fight and was only momentarily unconscious A few hours or a day or two later (the interval may be as long as several days or a week especially with venous bleeding) he develops headache of increasing severity vomiting drowsiness confusion seizures which may be one sided hemiparesis with slightly increased tendon reflexes and Babinski sign As coma develops the hemiparesis with Babinski sign may give way to flaccid or spastic limbs and Babinski signs bilaterally There may be aphasia Respirations become deeper and stertorous then shallow and irregular and finally stop The pulse is often slow (below 60) and bounding with a concomitant rise in systolic blood pressure The pupil may dilate on the side of the hematoma The cerebrospinal fluid is usually under increased pressure though normal and subnormal pressures do not exclude the possibility of an epidural hematoma The fluid may be clear or sanguineous depending on whether or not there is an associated contusion laceration or subarachnoid hemorrhage Death which is almost invariable if the clot is not removed surgically comes at the end of a comatose period rarely if ever in a conscious patient and is due to respiratory arrest The visualization of a fracture line across the groove for the middle meningeal artery and a knowledge of the side of the head struck (the clot is usually on that side) are of aid in diagnosis and of lateralization of the lesion

Epilepsy Posttraumatic epilepsy which occurs in 20 to 40 per cent of patients is one of the most dreaded complications of head injury Its basis is nearly always a contusion or laceration of the cortex The likelihood of epilepsy is said to be greater in parietal and posterior frontal lesions but it may arise from lesions in any area of the cerebral cortex The incidence of epilepsy is much greater in open than in closed head injuries Indeed in cases of pure concussion without contusion or laceration seizures are not much more frequent than in the general population The interval between the head injury and the first seizure averages about 9 months but it may be much longer particularly in children The longer the interval the less certain one is of its relationship to the traumatic incident There is a slightly greater tendency for those patients who had seizures at the time of head injury to become subject to recurrent seizures later The seizures are always of focal character or grand mal petit mal is rarely if ever due to trauma The significance of the different patterns of focal seizures which varies according to the location of the lesion has been worked out in detail by Penfield and his associates (see Chap 35) and by Russell et al The frequency of seizures in any given patient varies widely some patients have only a few others many with episodes of status epilepticus The EEG is of value in diagnosis a focus of spike or sharp waves is the characteristic finding Usually the seizures can be controlled by anticonvulsant medications and only the recalcitrant cases are likely to require excision of the epileptic focus The surgical results vary according to the methods of selection and technique of operation Seizures are abolished in less than 50 per cent by excision of the focus

Impairment of Mental Function Fortunately this is a rare sequela to head trauma Although mental function may be disturbed by focal lesions which produce dysphasia agnosia apraxia etc intellectual functions and memory are usually preserved This is true of even the most severe head injuries and is understandable when one considers the relatively small amount of brain tissue destroyed by the traumatic process The only exceptions to this statement are the few patients who survive a severe compression of the midbrain by a herniating temporal lobe and those with extensive degeneration of the cerebral white matter Children previously of low average or borderline intelligence and the aged who unnoticed had developed senile mental changes constitute other exceptions The aging person may have worked and functioned reasonably well until the time of the injury and afterwards is found to have a grave impairment of memory thinking and emotional control that permanently disables him That this is not simply a traumatic effect is indicated by the fact that the severity of the mental defect does not seem to parallel the severity of the head injury and as the months and years pass the mental disorder may progress (the natural course of brain trauma is one of sudden onset with maximal functional disturbance within minutes or hours and then improvement) This is one of the reasons why the prognosis in elderly adults is less good than for younger individuals

Posttraumatic Nervous Instability Undoubtedly the most troublesome sequela of head injury is that alluded to in the discussion of group 1 cases—*headache giddiness* and *nervous instability* This has been called the *postconcussional syndrome* or the *minor contusion syndrome* or *posttraumatic vasomotor neurosis* (Friedmann) All these terms are objectionable on the grounds that they suggest an explanatory hypothesis as yet unproved Headache is the central symptom usually at times localized to the part struck It is variously described as an aching throbbing pounding stabbing pressing pain and is remarkable for its variability The intensification of symptoms by mental and physical effort straining stooping and emotional excitement has already been mentioned Rest and quiet may relieve it Thus it becomes a major obstacle to convalescence which demands always a resumption of normal activities The dizziness is usually not a true vertigo but a giddiness The patient feels suddenly unsteady dazed weak or faint However a certain number of patients report symptoms which suggest a labyrinthine disorder For example objects in the environment are said to move momentarily and looking upward or to the side may cause a sense of unbalance Labyrinthine tests may show either hypo- or hyperreactivity or the results may prove to be normal The data are usually so indefinite that it is impossible to state whether or not the labyrinth and vestibular mechanisms have been injured Exceptionally vertigo is accompanied by diminished excitability of both the labyrinth and the cochlea and one may assume the existence of direct injury to the nerve or end organ The giddy patient usually is intolerant of noise emotional excitement and crowds Tenseness restlessness inability to concentrate a feeling of nervousness fatigue worry apprehension and an inability to tolerate the usual amount of alcohol complete the clinical picture In contrast to the multiple subjective symptoms detailed tests of intellectual functions and memory show little or no impairment This syndrome once established may persist for months or even years but usually the symptoms lessen as time passes It occurs in both sexes all races and at all ages excepting childhood There has been much controversy over its cause and to the present time its anatomic and physio

Treatment consists of placing burr holes and evacuating the clot before deep coma has developed

Subdural hygromas (collections of blood and cerebrospinal fluid in the subdural space) may also form after an injury as well as after meningitis (in an infant) and pneumoencephalography It is said that a tear of the arachnoid permits the accumulation of cerebrospinal fluid into the subdural space where it becomes trapped The patient may complain of severe headache drowsiness and confusion which are relieved when the subdural fluid is drained

Cerebral Hemorrhage (Immediate and Delayed) Acute massive brain hemorrhages are more frequent in elderly patients than in young ones and are usually fatal within a few hours The clinical picture is similar to that of hypertensive brain hemorrhage (deepening coma with hemiplegia a dilating pupil bilateral Babinski signs stertorous and irregular respirations) Indeed the problem that often cannot be solved even at post mortem examination is whether the patient had a hemorrhagic type of stroke and then fell or a fall that caused the hemorrhage If the bleeding is slow there may be an interval of 2 to 3 days between injury and the symptoms of the oncoming hemorrhage Coma or confusion if present from the time of the injury may obscure the signs of the intracerebral hemorrhage Craniotomy with evacuation of the clot has given a successful result in a few cases

Repeated Concussion (Punch Drunk) The cumulative effects of repeated injuries observed almost exclusively in professional boxers constitute a type of head injury difficult to classify for it has never been well studied pathologically It is a common observation that after a number of years in the ring pugilists often become forgetful slow in thinking and slightly dysarthric Their movements are stiff and uncertain especially those involving the legs there is unsteadiness of gait and occasionally there may be involuntary movements The plantar reflexes may be extensor on one or both sides The electroencephalogram shows slow waves of theta and sometimes of delta type The anatomic basis of this disease is unknown The postulation of showers of petechial hemorrhages from repeated blows on the jaws should not be given credence until demonstrated pathologically The findings of diffuse degeneration of the cerebral white matter in rabbits and monkeys which have been subjected to repeated concussions (Jakob) offer a more acceptable possibility

Sequelae of Severe Head Injury

The signs of focal brain disease whether due to open and penetrating or closed head injuries tend always to ameliorate as the months pass A hemiplegia is often reduced to a minimal hemiparesis or ineptitude of voluntary motor function with exaggerated reflexes and an equivocal Babinski sign on that side and aphasia improves to become a stuttering or hesitant paraphasia which is not disabling except in a professional worker or writer Many of the signs of brain stem disease improve often to an astonishing degree

Protracted Traumatic Coma and Pseudocoma Of particular interest is the outcome of those few patients who remain comatose for weeks or months or even years The authors have examined the brains of nearly a dozen cases of this type and nearly all have shown numerous foci of hemorrhage and ischemic necrosis in the midbrain and subthalamus especially in the tegmentum and tectum These were probably due in most instances to temporal lobe herniation and midbrain compression for one could see where one side of the base and tegmentum had been indented by the free edge of the tentorium In others there may have been direct injury to the midbrain and pons with numerous small hemorrhages Presumably these pathologic changes are not constant for scattered lesions in the cerebral cortex (contusions of the summits of convolutions ischemia with necrosis in the depths of sulci) and a remarkable diffuse degeneration of cerebral white matter have also been observed in cases of this type (Strich) These patients while comatose (i e unreceptive to stimuli and unresponsive) or while in a state of pseudocoma (receptive and capable of signaling by blinking their eyes but otherwise unresponsive) usually exhibit a variety of neurologic abnormalities unequal pupils dilated fixed pupil and oculomotor palsy on one side and hemiplegia on the other disturbances of gaze bilateral pyramidal paralysis with Babinski signs extensor postures of arm and leg on one side and flexed arm and extended leg on the other brain stem attacks (extension of limbs increased respiration blood pressure and sweating on stimulation of any kind) and involuntary movements (tremor chorea athetosis) Some remain in this reduced mental state until death (nearly 10 years in one of the authors cases but usually a few months or a year or two) The majority however may regain enough function to leave the hospital a few surprising as it may seem are restored to full alertness and adequate mental function Residual weakness of limbs slurred speech ocular palsies ataxia of an arm or leg or involuntary movements are frequent During convalescence language mechanisms may be disturbed in various ways There may be mutism akinesia or adynamia (lack of volition or impulse to speak or move) dysarthria and if there are contusions of the cortex of the dominant hemisphere an aphasia as well Any one or a combination of these abnormalities may be present

tained and recorded Verbatim statements should be *written down whenever possible*

The treatment problems presented by each of the three groups of clinical cases discussed above are as follows

Minor Head Injury In this group are included patients who (1) were never unconscious at any time (2) were briefly unconscious but are mentally clear at the time of the first examination (3) are rapidly regaining consciousness

Circumstances dictate how each case is managed If the injury was trivial and the scalp was not lacerated and if the patient is entirely clear mentally little or nothing need be done When the patient is unable to give an accurate account of what has happened and appears still to be somewhat confused or incoherent he should be compelled to lie down or at least remain in one place It often happens that the confusion is not detected and the patient is permitted to resume activity while still acting in an irrational manner He may get into his car and attempt to drive only to have another accident or he may continue to play a game and make a series of errors

When a conscious or nearly conscious patient is admitted to a general hospital it is tempting to let him go his way Experience teaches caution however *A complete examination* with the patient fully undressed should be carried out It is well if there is any likelihood of litigation to obtain x rays of the skull and an electroencephalogram The question of lumbar puncture will usually depend on how serious the injury was on the prominence of posttraumatic headache etc The patient should probably be detained for a few hours or overnight in order to make sure that he is not merely in a lucid interval The first few hours or days may be spent in the hospital If this cannot be arranged and he is sent home a member of the family should be charged with the responsibility of reporting any important change such as increasing headache vomiting drowsiness confusion or seizure Their occurrence would dictate hospital entry *for further examination* an x ray of the skull and possibly a lumbar puncture A posttraumatic headache and drowsiness may be the first signs of an oncoming epidural or subdural hematoma On the other hand they may reflect only what is presumed to be a localized edema Further observation will usually distinguish between these conditions Observation may be safely continued as long as the patient remains conscious Here one may proceed on the rule that the life of the patient with a head injury is never in jeopardy as long *as he is mentally clear and responsive* The only exceptions to this statement are rare instances of fracture through the foramen magnum with contusion of the inferior surface of the cerebellum and with swelling of tissue and herniation through the *foramen magnum* Two of the authors patients with this condition died unexpectedly after a period of intense occipital headache at a time when they were quite alert The management of posttraumatic headache dizziness and nervous instability which often follow relatively minor injuries to the head will be discussed below A simple fracture without involvement of paranasal sinuses requires no special treatment but is believed to contraindicate vigorous athletic activities *for several months* or a year

Patients Who Are Unconscious When First Seen If the physician arrives on the scene of the accident a hurried examination should be made before the patient is moved in order to determine whether there is dangerous hemorrhage from a laceration of the scalp or other parts of the body and whether there is likelihood of a fracture dislocation of the cervical spine which is occasionally associated with head injury If the patient is in shock with cold clammy skin and feeble pulse he *should be covered with warm blankets* In moving an individual with a potential cervical spine injury the spine should be kept straight at all times and flexion of the neck should be avoided This can best be done by placing sand bags or firm pillows *on either side of the head and warning every* one against neck flexion An even safer method is to place the patient on a stretcher face down and arrange pillows to assure a clear airway Bleeding from the scalp can usually be controlled with a firm pad unless an artery is divided and then a suture becomes necessary

In the hospital where all such patients should be taken the first steps should be to control shock This can usually be done by the application of warmth keeping the head low and leaving the patient alone for a few minutes The shock will usually come under control in a few minutes with or without vasopressor drugs or transfusions Persistent shock is rare in head injury and always raises the suspicion of a ruptured viscera with internal bleeding *extensive fractures* or traumatism of the cervical spinal cord A quick survey will enable one to estimate the depth of coma size of pupils and presence of obvious fractures and if shock is not present, or after the blood pressure has stabilized a more detailed examination can be performed The skull should be carefully inspected and palpated The hair should be cut off around the scalp wound A bogginess of the temporal or postauricular region (Battle s sign) bleeding from the nose or ear extensive conjunctival edema and hemorrhage are useful signs of underlying skull fracture However it *should be remembered* that rupture of the eardrum or a blow on the nose may also cause bleeding from the ear and nose re

logic basis has not been settled The constancy of the symptoms their appearance in individuals who have had no trace of neurosis prior to the accident and their relationship to physical and mental activity have led most neurologists to view this syndrome as a manifestation of a specific morbid process in cranial structures Nevertheless the striking reduction in disability when the physician gives firm reassurance and encourages early rehabilitation leaves little doubt as to the existence of important psychologic mechanisms at least for the maintenance of the symptoms And if compensation is involved the motivation to return to previous activities is still further impaired

Extrapyramidal and Cerebellar Disorders The question of *posttraumatic Parkinson s syndrome* has been discussed many times usually with the general conclusion that a true traumatic parkinsonism does not exist Most patients have merely had paralysis agitans or postencephalitic Parkinson s disease brought to light by head injury The head injury may have been severe or trivial and the course of the illness is usually progressive just as it is in the nontraumatic cases Patients who survive a severe midbrain syndrome manifested in the beginning by protracted coma may have a clinical picture which bears some similarity to Parkinson s syndrome but the presence of ocular palsies nystagmus and unilateral or bilateral pyramidal signs should permit easy distinction One should be equally skeptical regarding the existence of a posttraumatic cerebellar ataxia

Posttraumatic Hydrocephalus Rare examples of posttraumatic hydrocephalus with intermittent headaches vomiting confusion and drowsiness have been reported and autopsy has demonstrated an adhesive basilar meningitis attributed to subarachnoid or ventricular hemorrhage Since a symptomatology like this has been observed occasionally after the rupture of a saccular aneurysm with massive subarachnoid hemorrhage due presumably to blocking of the aqueduct and fourth ventricle by blood clot this mechanism has also been suggested as a possible explanation of traumatic hydrocephalus in patients with cerebral contusion However there are other patients with enlarged ventricles who probably at no time had a significant degree of subarachnoid and ventricular hemorrhage The mechanism of the hydrocephalus in these cases is not known

Posttraumatic Psychiatric Disorders In contrast to nervousness and nervous instability which are common sequelae of injuries of all types posttraumatic psychoses are relatively infrequent Adolph Meyer whose study of traumatic insanity is still a standard reference encountered this type of illness in approximately 1 per cent of admissions to a state hospital Statistics from military files and civilian hospitals show that about 1 of every 100 patients with a head injury exhibits a behavioral change which requires incarceration in a mental hospital (the figure is lower for military head injuries 1 in every 1 000 cases) These terms traumatic psychosis and insanity have been used in various ways which makes any summary of data and opinion difficult From the psychiatric standpoint many of the posttraumatic states already described (traumatic stupor delirium confusion or dementia) would be classified as "defect psychoses" Other physicians use this term as it is used here to designate aberrations of behavior which prevent the patient from resuming his place in society The most distressing psychiatric syndromes have been suspiciousness and paranoid delusions unaccountable outbursts of violent temper sometimes with homicidal or suicidal tendencies progressive hyperactivity delirium and mania and episodes of bizarre behavior with subsequent amnesia reminiscent of temporal lobe seizures Alcoholism may provoke some of these behavioral abnormalities Some of these illnesses are undoubtedly due to residual brain damage in individuals of peculiar personality make up However attempts to account for psychoses of this type by reference to constitutional peculiarities and predisposition laid bare so to speak by head injury have not been convincing They may be said to represent first attempts to find working hypotheses Some patients afflicted with these psychoses remain helplessly disabled In others the outcome has been surprisingly good and the patient after some months in a psychiatric hospital has been able to return to his home and his former job

Clinical Approach to the Patient Who Has Suffered Head Injury Suggested Plan for Management

The physician who undertakes to treat the head injury case must at all times bear in mind that assiduous attention to detail may prove to be lifesaving and that accurate documentation of all diagnostic findings and therapy is desirable if the medical data are later to be used in the arbitration of insurance claims worker s unemployment compensation etc The suggestions which follow can do no more than serve as guides for every patient presents a combination of problems that the physician has not encountered before and may not observe again in identical form

Exact data concerning the patient s medical status before the accident (previous illnesses work and social record emotional stability) the nature and precise circumstances of the accident the duration of retrograde and anterograde amnesia and all that transpired afterwards should be ob

minimize the seriousness of his head injury and to reassure him that he will recover Early rehabilitation should be encouraged It may safely begin as soon as the cerebrospinal fluid becomes clear usually within a few days or 1 to 2 weeks at the most except of course in the rare cases of protracted coma.

Posttraumatic headache giddiness and nervousness are the most difficult symptoms to manage during this period Careful explanation of the symptoms an optimistic prognosis and the institution of a program of graded mental and physical activities to the point of tolerance stand the best chance of restoring the patient to a useful life The patient should be told that he must expect a certain amount of headache and should carry on in spite of it Meprobamate 200 mg t i d is useful for anxiety and a non habit forming analgesic medication should be given for the more severe headaches (Empirin or aspirin) Insomnia may require a barbiturate medication or chloral hydrate at first but they should be discontinued as soon as possible Any litigation that may be involved should be settled within 6 to 9 months To delay settlement usually works against the best interests of the patient. The severity of his injury can be ascertained within this period of time and a longer period of observation only enhances his worries and fears and reduces his motivation to return to work

The prognosis of head injury in good hands is influenced by several variables Elderly patients often remain disabled especially when compensation is involved Young and middle aged adults do better if they are not entitled to compensation (Russell's figures 70 per cent of compensation cases back at work in 18 months 83 per cent of noncompensation cases working at the end of this period) Russell also pointed out that the severity of the injury as measured by the duration of traumatic amnesia was a factor If the period of amnesia was less than 1 hr 95 per cent of cases were back at work within 2 months if longer than 24 hr only 80 per cent had returned to work in 6 months About 60 per cent, however still had symptoms at the end of 2 months and 10 per cent at the end of 18 months

INJURIES OF THE SPINE AND SPINAL CORD

Injury to the spinal cord is not infrequent in both civilian and military life It may be the sole complication of an injury or as indicated above it may be combined with head injury Although the primary consideration is whether the spinal cord or spinal roots have been damaged some reference to the nature of vertebral injury is necessary for an understanding of this type of traumatic disease

Varieties of Spinal Injury

A useful classification of spinal injuries is one which divides them into fracture-dislocations pure fractures and pure dislocations The relative frequency of these types is about 3 1 1 Direct violence to the spine is an uncommon cause of vertebral disruption except for stab and bullet wounds most spine injuries are the result of force "applied at a distance" All three types of injury are produced by a similar mechanism usually a vertical compression of the spinal column to which flexion is almost immediately added The two important variables in the mechanics of vertebral injury are the nature of the bones and the strength direction and point of impact of the force

The Nature of the Vertebral Body As lucidly explained by Jefferson, the vertebral column consists of two parallel, fused cylinders of different structure and serving different purposes The anterior column is comprised of the vertebral bodies and intervertebral cartilages whose general purpose is weight bearing The posterior cylinder is an articulated column of neural arches giving protection to the spinal cord From the neural arches arise a number of transverse and spinal processes which provide for muscular attachment Of these two columns or cylinders the anterior is more compressible being constituted of very little compact and much cancellous bone Thus a compressive force usually causes wedging of a vertebral body and is followed by flexion Wedging or collapse of vertebral bodies is most to be expected where they are high and spongy and separated by thick intervertebral disks i e in the lower thoracic and lumbar spine Wedging is seldom complete in the cervical region because violence to the neck in a vertical direction is not applicable without movement of the spine part of the force of the blow being converted into a movement of flexion

***Strength, Direction* and Point of Impact of the Force** If the injuring body striking the cranium is hard and the velocity is high a skull fracture occurs the elastic quality of the skull absorbing the force of the injury If the injuring body is soft yet heavy the spine and particularly its cervical portion will be the part injured If the neck happens to be rigid and straight and the force is quickly applied to the head, the atlas and the odontoid process of the axis may break If the force is not so quickly applied and removed an element of flexion occurs Flexion movement plus a vertical force constitute the essential factors in fracture-dislocation or pure dislocation These types of injury are most *frequent* in the cervical region.

spectively Fractures of the orbital bones may cause displacement of the eye with resulting diplopia and fracture of the jaws disalignment of the teeth and great discomfort on attempting to open the mouth Careful notes should be made regarding temperature pulse blood pressure state of consciousness pupil size ocular movements corneal reflexes facial movements during grimace swallowing *tone of limb muscles movements of* limbs predominant postures and reflexes Vital signs and consciousness should be checked and recorded by the nurse or physician every 2 hr A proper airway must be maintained The best position for the patient is supine with the head on a pillow and turned to one side If urine is retained and the bladder distended a catheter should be inserted and kept there If coma persists for more than 12 to 24 hr a nasal tube should be passed and fluids and nourishment given by that route Intravenous fluids should be administered slowly and not in excessive amounts even hypertonic glucose may increase oncoming pulmonary and cerebral edema the danger of the latter being especially great in children Lumbar puncture should *be done as soon as practicable for* diagnostic purposes (immediately if bacterial meningitis is suspected) and if the pressure is elevated it should be lowered to 100 to 150 mm Daily lumbar punctures have their advocates and their opponents The authors have tended to use them only if the *pressure is elevated and the patient s* condition is not improving Hypertonic solutions ($MgSO_4$ 90 Gm and water 180 ml) may be given per rectum after a cleansing enema and held for 30 min or if the patient can swallow 60 ml of this solution may be given by mouth every hour until a loose bowel movement is obtained Hypertonic solutions intravenously are of less certain therapeutic value Fifty to one hundred milliliters of 50 per cent glucose or hypertonic sucrose may be injected intravenously if operation is to follow within a few hours but otherwise should probably not be given for there may be an even higher cerebrospinal fluid pressure after their hypertonic effect wears off X rays of skull and other parts should be taken after the first day or two unless there is a suspicion of an epidural hemorrhage in which case they should be made at once to visualize a crack across the course of the middle meningeal artery Restlessness is controlled by sodium phenobarbital or paraldehyde but only if careful nursing does not quiet the patient and permit him to sleep for a few hours at a time

Once the patient has regained consciousness the danger of suffocation aspiration pneumonia bronchopneumonia thrombophlebitis and pulmonary embolism has usually passed and therapy can proceed along the lines indicated for the first group

It is often stated that death from head injury during the first 12 to 24 hr is the direct effect of primary brain injury and cannot be prevented The advisability of any surgical *procedure during this* period is much debated If the patient survives for one two or more days and remains in coma the control of brain swelling and hemorrhage by surgical means must be considered Should the condition *of the patient then begin to deteriorate* (pulse rising temperature subnormal or rising state of consciousness worsening hemiplegia more obvious plantar reflexes more clearly extensor) a decision must be made concerning an epidural or subdural hemorrhage and of increasing brain edema with temporal lobe herniation Rowbotham who has had a large experience with cases of this type recommends a right sided temporal decompression and two inspection burr holes in the left one at the Sylvian point and one at the parietal eminence for some of these patients In his opinion the indications for surgery are (1) retrogression following a period of improvement which cannot be controlled by lumbar puncture and oral and rectal hypertonic solutions or intravenous dehydration *measures (2) decerebrate* rigidity which has its onset after an interval of 24 hr (early decerebrate rigidity implies primary brain stem injury) if meningitis is ruled out (3) a dilated fixed pupil on one side with no improvement after 12 hr (4) prolonged unconsciousness associated with a persistently *high cerebrospinal fluid pressure* Not all neurologists and neurosurgeons are agreed on the value of surgical decompression but certainly the removal of a large epidural or subdural hemorrhage which cannot be diagnosed easily in the comatose patient may be a lifesaving procedure

The treatment of the patient with protracted coma is too complex to be outlined in detail here. The reader should refer to p 1770 Every patient presents special problems which must be dealt with as intelligently as possible

Patients Who Temporarily Recovered Consciousness (Lucid Interval) and Then Became Stuporous or Comatose The treatment is that of epidural *subdural and delayed cerebral hemorrhage* This has already been discussed

General Convalescence

A head injury carries dire import to most lay individuals who often fear for their mind and are concerned about their capacity to resume their place in society In former times therapeutic measures often involved *long discussions of the serious*ness of the injury protracted bed rest and inactivity all of which served only to engender greater anxiety Even worse these measures were not of proved value It is now widely acknowledged that the patient does better if his physician tends to

extensor spasms with sweating and micturition all occur after stimulation of the skin viz the *mass reflex* This stage of reflex activity may last for years unless sepsis intervenes in which case the state of spinal shock may return

Less complete lesions of the spinal cord may result in little or no spinal shock or extensor spasm incomplete voluntary motor paralysis a flaccid atrophic paralysis variable sensory impairment in the arms and a spastic weakness of the legs and a partial or complete Brown Sequard syndrome are some of the resulting clinical pictures

The final result may be permanent and complete disability rarely consistent with survival for more than a short time (days to weeks) or a gradual improvement and complete or almost complete recovery may occur Any residual symptoms after 6 months are likely to be more or less permanent

The level of the cord lesion can be determined by the clinical picture A complete paralysis of arms and legs usually indicates a dislocation at the fourth to fifth cervical If legs are paralyzed and arms can be abducted and flexed the dislocation is likely to be at the fifth to sixth cervical Paralysis only of hands and of legs indicates the level of vertebral disorder to be the sixth to seventh cervical When the motor paralysis involves muscles above the knees and sensory loss includes the twelfth thoracic dermatome the site is the eleventh to twelfth thoracics If the paralysis is below the knees and the first lumbar escapes the lesion is at the twelfth thoracic first lumbar vertebrae Prognosis for the latter preponderately a cauda equina lesion is better than for the former

Treatment

In general the treatment of spinal cord injuries is conservative and symptomatic When there is x ray evidence of bony displacement or of bone fragments pressing on the cord or when spinal subarachnoid block is present the cord should be decompressed by laminectomy This should not be undertaken however until the patient has recovered from shock If the spinal cord injury is associated with dislocation of the vertebrae traction on the neck is necessary to secure proper realignment This is accomplished by a head halter attached through the head of the bed over a pulley to a weight of 10 to 15 lb There are other more complicated techniques such as tongs which fasten onto the skull (Crutchfield) In thoracic crush injuries hyperextension can be maintained by placing a narrow pillow under the affected area Traction should be continued for 4 to 6 weeks and then a brace may be substituted The aftercare of patients with paraplegia and disturbance of vesical or rectal function is similar to that of patients with like symptoms from other causes (see Chap 272) Tidal drainage is a valuable adjunct in preventing infection stone formation and contracture and in securing return of function Daily enemas are usually the most effective means of controlling fecal incontinence Physiotherapy muscle reeducation and the application of proper braces are all important in the rehabilitation of the patient

INJURIES TO SPINAL ROOTS PLEXUSES AND PERIPHERAL NERVES

Discussions of these subjects will be found in Chaps 253 and 260

In conclusion it may be said that head and spine injuries should invite the attention of general physicians internists and neurologists There are many important lessons to be learned about the function of the human nervous system from following these cases Their treatment except in a minority of cases where there is laceration of scalp depressed fracture epidural and subdural hemorrhage or compression of the spinal cord must be conducted largely along medical lines

Another mechanism of spinal injury occurring most often in military life is that in which missiles of high velocity pass through the vertebral canal and destroy the spinal cord In some cases they may strike the vertebral column without entering the spinal canal and agitate it so violently that the cord suffers injury The term given the temporary spinal paralysis which results is *spinal concussion* This condition may also be produced by violent falls flat on the back

A study of 2 006 cases collected from the literature by Jefferson shows that most vertebral injuries occur at the first to second cervicals fourth to sixth cervicals and eleventh thoracic to second lumbar vertebrae Industrial accidents most often involved the dorsolumbar vertebrae and those caused by falling either in a sitting position or with head down as in diving accidents affect the cervical region In the authors neuropathologic material which contains 26 cases the usual circumstances of spinal injury were a state of alcoholic intoxication and a fall down a flight of stairs auto accidents crushing industrial accidents gunshot or stab wounds and birth injury in that order of frequency The majority of these fatal cases were fracture dislocations or dislocations of the cervical spine

Mechanism of Spinal Cord Injury

The spinal cord may escape injury even though there is vertebral dislocation especially in regions where the spinal canal is large i e in the cervical and lumbar regions Or the spinal cord may be damaged without radiologic evidence of fracture or dislocation One cannot easily determine the full extent of spinal injury however even at autopsy because of difficulty in examining the vertebrae By far the most satisfactory technique for demonstrating the degree of spine injury and the presence of a tearing of ligaments with dislocation is the x ray taken laterally with the neck flexed and extended The most frequently established mechanism is a vertebral dislocation with or without fracture The upper vertebrae are displaced anteriorly and there is a break in posterior longitudinal ligament and intervertebral disk Or a sudden extension of the neck the so called whip lash injury may occur The spinal cord is most often subjected to a shearing force between the pedicles of the vertebra above and the body and laminae of the vertebra below the dislocation or is sharply angulated in violent extension of the neck Agitation of the spine as when it is struck in some part by a bullet has been postulated as a means of spinal concussion This has led to much confusion because the term is not employed here in the usual sense of a transient interruption of neural function by trauma without perceptible structural change

Pathology of Spinal Cord Injury

As a result of squeezing or shearing of the cord there are necrosis of fiber tracts and gray matter and a variable amount of hemorrhage chiefly in the more vascular gray matter These changes are maximum at the point of injury and one or two segments above and below it Rarely is the cord cut in two and seldom is the pia arachnoid lacerated This condition is best designated as *traumatic necrosis of the spinal cord* Separation of such pathologic entities as hematomyelia concussion contusion and hematorrhachis is rarely of value either clinically or pathologically As with most lesions the total disease picture is compounded of an irreversible structural lesion and a disorder of function each of which may vary in degree The extent and permanence of the clinical manifestations are determined by the relative amounts of these two An exception to this statement might be made for gunshot wounds of vertebrae Here the explosive force of the missile may shatter myelinated fibers without dislocation of vertebrae

Clinical Effects of Spinal Cord Damage

The description of traumatic paraplegia by Riddock cannot be excelled He divides the clinical picture into two stages as follows

Muscular Flaccidity or Spinal Shock The loss of function which is inflicted at the time of injury (an immediate and complete flaccid paralysis of limbs i e fourth to fifth cervical quadriplegia thoracic injury paraplegia paralysis of bladder and bowel sphincters and loss of sensibility below the level corresponding to the spinal lesion) is accompanied by a complete or almost complete suppression of reflex activity of all spinal segments below the lesion This condition is the so called "spinal shock The plantar reflexes are at first variable and may be flexor or extensor The lower extremities lose heat if left uncovered and swell if dependent Sweating is abolished Cutaneous ulcerations may develop over bony prominences Urine and feces are retained to the point where involuntary overflow or leakage results Occasionally there is priapism because of venous congestion A paralytic ileus may occur

Reflex Activity If the lumbosacral segments are undamaged spinal shock wears off in 2 to 3 weeks The first sign of this is contraction of the hamstrings with flexion or extension of the toes on plantar stimulation Then gentle and later strong involuntary flexor spasms make their appearance Ankle jerks and then knee jerks return Retention of urine and feces becomes less complete and at irregular intervals urine is expelled by active contraction of the detrusor muscle Reflex defecation and sweating also return At times flexor spasms and later ex

stance of the brain owing to some fault in embryologic development e g ectodermal cells from skin or mucous membranes which give rise to Rathke pouch cysts craniopharyngiomas and cholesteatomas or lipocytes from which the rare lipomas arise

Finally there is a group of tumors which affect the brain secondarily that is to say they arise in some other tissue and extend to the brain and rarely the spinal cord Of these there are two groups—those which reach the nervous tissues via the blood stream i e metastasize such as the carcinoma and the sarcoma and those which have their source in the epidural and osseous tissues that envelop the brain and which invade the meninges and cerebral tissues by direct extension e g chordoma osteoblastic sarcoma lymphocytoma lymphoblastoma plasmocytoma Hodgkin s granuloma and sarcoma etc

For the student of medicine the most important facts to know are (1) that many types of tumor occur in the cranial cavity and spinal canal and that certain ones are much more frequent than others (see pp 1624 to 1636) (2) that some of these tumors such as the craniopharyngioma meningioma and Schwannoma have a disposition to grow in certain parts of the cranial cavity (3) that their growth rates vary some like the glioblastoma being highly malignant others like the meningioma being benign and (4) that there are differences in the growth behavior of these several tumors some being invasive others compressive These pathologic peculiarities are important for they have valuable clinical correlations providing the explanation of slowly or rapidly progressive clinical states excellent or poor prognosis after surgical excision etc It is for these reasons that the clinician is encouraged to learn a histologic classification and to think always in terms of particular types of intracranial and intraspinal tumors

The one place where these pathologic clinical correlations tend to fail is in the glioma group of tumors i e astrocytoma—glioblastoma multiforme etc and this is regrettable because they are so common Often these gliomas are of mixed cell type For example one part of the tumor may be a typical astrocytoma and another an oligodendrocytoma Also the degree of differentiation or its opposite the degree of anaplasia varies from one part of the tumor to another As would be expected with such heterogeneous growths a biopsy sample is often quite misleading with reference to the expected clinical behavior of the tumor For example the clinician may be led to believe that a tumor which in a biopsy is composed of astrocytes is benign whereas actually the main mass of it still in the brain is a glioblastoma or a small nodule of glioblastoma in an excised specimen may suggest a hopeless prognosis when actually the remainder of the tumor in the brain is a well differentiated astrocytoma

The classification given here is modified from that of the Spanish histologist Rio del Hortega It represents his last great contribution to medical science and is based on a meticulous study by silver impregnation methods of the cell types of nearly a hundred brain tumors

CLASSIFICATION OF INTRACRANIAL AND INTRASPINAL TUMORS

I Primary tumors of
- A Nervous parenchyma
  - 1 Blastomas of glial origin
    - *a* Glioblastomas (isomorphic heteromorphic)
    - *b* Astroblastomas
    - *c* Astrocytomas
    - *d* Ependymoma (glioepitheliomas)
    - *e* Oligodendrocytomas
  - 2 Blastomas of neuronal origin
    - *a* Neuroblastomas (some medulloblastomas)
    - *b* Neurocytomas
- *B* Meninges
  - 1 Meningioma or arachnoidal fibroblastoma (meningoexothelioma)
  - 2 Fibroblastomas
  - 3 Reticulum cell sarcomas
  - 4 Hemangioblastomas (including Lindau s cyst)
  - 5 Other e g melanocarcinomas
- *C* Hypophysis and Rathke pouch
  - 1 Chromophobe chromophil adenomas of pituitary gland
  - 2 Craniopharyngiomas etc
- *D* Developmental origin ("rest cell" tumors)
  - 1 Teratomas
  - 2 Epidermoids (cholesteatomas) and dermoids
  - 3 Lipomas
  - 4 Angiomas (vascular malformations)
- *E* Adnexal organs in the brain
  - 1 Choroidal tumors (papillomas epitheliomas adenocarcinomas)
  - 2 Pineal tumors or pinealomas (pineocytomas pineoblastomas)
- *F* Nerves
  - 1 Neurinomas
  - 2 Neurofibromas
  - 3 Plexiform neuroma

II. Secondary tumors (cranial spinal, extracranial extraspinal)
- A Those arising outside the central nervous system and metastasizing via blood stream
  - 1 Carcinoma (most frequent lung breast, kidney colon infrequent stomach bile ducts liver thyroid testicle ovary uterus hardly ever metastasize to the brain prostate esophagus pancreas skin mucous membranes)
  - 2 Sarcoma (rhabdomyosarcoma osteogenic sarcoma leiomyosarcoma fibrosarcoma)
- *B* Those arising in cranial bones and enclosed para

256 TUMORS OF THE BRAIN AND SPINAL CORD

Henry de F Webster and Raymond D Adams

Tumors of the central nervous system play a very important part in neurologic medicine and occupy a distinct field by themselves It may be said of them generally that they occur in great variety are dangerous (malignant) because of size location and invasive qualities usually destroy the tissues in which they are situated and displace those around them are a frequent cause of increased intracranial pressure and are often lethal

During the first half of the twentieth century a great deal was learned about the gross and microscopic features of these tumors Also a number of classifications were introduced the most notable being those of Bailey and Cushing Hortega and Kernohan However little has been found out about their fundamental nature The experimental work done in animals in which tumors have been induced by chemical substances and the bacteriologic biochemical histologic and tissue culture studies of tumor tissue obtained from human beings during operation or post mortem have unfortunately shed little light on the fundamental problems of etiology and pathogenesis Trauma viruses chemical irritation and heredity have been suggested as causative agents but no convincing evidence on these points has been accumulated

Probably the most singular advances in this field during the present century concern diagnosis and treatment The standard textbooks of neurology written before 1900 (Osler Strumpell Oppenheim Gowers) and the monographs containing the brilliant lectures on nervous disease by Hammond Charcot Romberg Duchenne and Gowers (the reader may satisfy himself) reveal that tumor of the brain and spinal cord rarely figured in the thinking of these great clinicians Moreover it was not until 1879 that Macewen diagnosed and operated on the first intracranial tumor and shortly thereafter that Sir Victor Horsely explored the possibilities of intracranial surgery By the turn of the last century barely 50 cases had been operated upon successfully The great developments achieved within the modern era of medicine must be credited largely to Harvey Cushing and his students who showed the feasibility of removing intracranial growths and who worked out the necessary technical details of diagnosis and operative surgery Their work was aided immeasurably by the use of air to visualize the ventricular system and subarachnoid spaces [the pneumoencephalogram (PEG) and ventriculogram of Dandy] the development of arteriography (Moniz), and the invention of electrocoagulation the sucker and the Gigli saw More recently radioactive isotopes have been exploited by a number of American investigators (Moore Sweet and others) for the purpose of localizing tumor growths

CLASSIFICATION

The classification of the tumors of the nervous system like that of tumors of other viscera is primarily regional and histogenetic Subdivisions are based on the cells of origin The embryologic studies of His Cajal Hortega and their students established the existence of 14 important cell types within the cranial cavity the astrocyte oligodendrocyte microgliacyte ependymal cell choroidal epithelial cell nerve cell fibroblast specialized arachnoidal fibroblast Schwann cell histiocyte vascular endothelial cell pituitary epithelial cell pineal epithelial cell and meningeal melanophore cell Each of these basic type cells is capable of giving origin to a series of tumors which grow at various rates of speed and all gradations can usually be found between the slowest and fastest growing The tumor cells tend to differentiate as do the cells from which they arise If the growth rate is slow differentiation may be perfect just as it is in normal tissues and there is no difficulty in determining the type If the growth rate is rapid the differentiation is less complete or entirely lacking and recognition of the type cell in microscopic sections may be nearly impossible

In the first part of the classification given below the tumors are arranged in order of frequency and their terms are formed by affixing oma to the name of the cell of origin viz astrocytoma oligodendrocytoma microglioblastoma neurocytoma fibroblastoma histiocytic sarcoma etc However if the tumor cell is poorly differentiated it has become the accepted practice to denominate the tumor by the name of the embryologic precursor of that cell A poorly differentiated astrocytoma thus is called a glioblastoma an oligodendrocytoma becomes an oligodendroblastoma a neurocytoma is referred to as a neuroblastoma Special terms have had to be introduced to denote tumors whose cell of origin is uncertain but has resemblance to some particular embryologic element e g the medulloblastoma is used to designate the small cell tumor of the cerebellum in children believed to be derived from the indifferent cells of Schaper In general as with all tumors the less the degree of differentiation the greater the malignancy

In addition to the tumors derived from these 14 type cells others originate from cells ordinarily not part of the nervous system They may arise from cell rests" that are left in the meninges or sub

spaces Soon however the limits of these adjustments are surpassed and the pressure throughout the ventricles and in all parts of the subarachnoid space rises Presumably the veins in the cerebral tissues adjacent to the tumor are compressed with resulting increase in capillary pressure locally—the conditions necessary for *regional swelling* or *edema* In as much as any general increase in the cerebrospinal fluid pressure is immediately transmitted to thin walled veins the pressure in the subarachnoid space and veins is nearly the same at all times If the rise in cerebrospinal fluid pressure is slow the stasis of blood resulting from this elevated venous pressure can be compensated for by vasodilatation of arteries and arterioles and cerebral circulation is unimpaired If the rise is rapid and to high levels approaching diastolic blood pressure the blood pressure must rise usually the systolic more than the diastolic in order to maintain cerebral blood flow As a rule this is accompanied by a slow bounding pulse Under these conditions the velocity of cerebral blood flow again approaches normal Presumably these circulatory reflexes which result in the rise of blood pressure and bradycardia are initiated by venous stasis and accumulation of carbon dioxide in the vasomotor center in the medulla oblongata The respiratory centers also become affected for increases in intracranial pressure usually cause an irregularity and finally a cessation of respiration

These changes in blood pressure pulse and respiration which were studied by Kocher and by Cushing in 1901 are of the greatest importance in the clinic for they may afford valuable clues as to the existence of increased intracranial pressure Not less valuable is the papilledema or "choked disk" that can be seen with an ophthalmoscope in the optic fundi of most patients who have elevated intracranial pressure of more than a few days standing The papilledema is best accounted for by the high pressure in the subarachnoid space surrounding the optic nerves The veins that drain the retina as they course back along the optic nerves en route to the cavernous sinuses are blocked creating a lymphedema of the nerve head

Raised intracranial pressure due to a mass or enlargement of the ventricles (blockage of cerebrospinal fluid circulation) when severe causes obtundation of cerebral function This is manifested clinically by a number of characteristic symptoms (see p 296) and electroencephalographically by diffuse slowing of the electrical activity of the cortex

Another extremely important anatomic fact is that the closed cranial "box" is subdivided into fairly rigid compartments by two infoldings of dura mater one the falx which lies between the two cerebral hemispheres and the other the tentorium which separates the cerebellum from the occipital lobes These anatomic arrangements and the opening at the base of the skull through which the spinal cord and medulla are joined leave three important apertures the foramen magnum the tentorial opening or notch" and the subfalcial or supracallosal space A tumor growth in one compartment say the right middle cranial fossa, raises the pressure in that compartment more than in the others and either brain or tumor tissue tends to be displaced along lines of least resistance i e through the subfalcial space to the left half of the cranial cavity and through the tentorial opening into the posterior fossa on the right side These brain displacements are exceedingly dangerous and contribute as a rule to the death of the patient in most cases of intracranial tumor abscess trauma and subdural and epidural hemorrhage The temporal lobe–tentorial hernia is said to stretch the ipsilateral oculomotor nerve (Hutchinson s pupil—a dilated pupil on the side of a lesion and also a drooping eyelid) to displace and compress the midbrain with resulting stupor or coma bilateral pyramidal signs (often greater on the side of the hernia) decerebrate postures of extension of all four extremities and perhaps irregularity and final arrest of respiration and to distort and partially block the aqueduct of Sylvius and to narrow the perimesencephalic subarachnoid space with hydrocephalus and rising intracranial pressure Also the posterior cerebral arteries may be occluded on one side or both sides with infarction of the occipital lobes The cerebellar–foramen magnum pressure cone (herniation of cerebellar tonsils) in which the cerebellar tissue or tumor mass is displaced into the cervical spinal canal with compression of the medulla oblongata results in tilting or altered posture of the head dilated pupils impairment of consciousness and death due to respiratory arrest The physiologic and clinical effects of subfalcial herniation are not known

Herniation of the floor of the third ventricle and adjacent parts of the brain into the sella turcica may if acute be accompanied by marked reduction in vision and if chronic cause enlargement of the sella and atrophy of the pituitary gland

A knowledge of these effects of elevated intracranial pressure and of the herniations and displacements of tissue is necessary if one is to understand the clinical behavior of intracranial growths Symptoms and signs of brain tumor depend not on the invasion and destruction of important nervous structures alone but also on the pressure phenomena

Clinical and Pathologic Characteristics

As was pointed out by Bailey the intracranial tumors are far too heterogeneous to be treated as a whole The origin structure symptoms and

nasal sinuses vertebral bodies and epidural tissues

1. Carcinoma of paranasal sinuses
2. Transitional cell epitheliomas from tissue of pharynx
3. Metastatic carcinomas which metastasize to bone (prostate breast thyroid etc)
4. Multiple myeloma and plasmacytoma and other lymphomas including Hodgkin s disease
5. Chloroma
6. Chordoma
7. Osteogenic and fibrosarcoma of bone

Implicit in the histogenetic theory is the notion first advanced by Cohnheim—that the type cell from which the tumor originates is a primitive undifferentiated element that has resided within the nervous system since the earliest embryonal period. This is a likely explanation of certain teratomas dermoids hamartomas and other tumors apparently derived from cell rests but there is no evidence that this hypothesis is applicable to the gliomas and meningiomas. Indeed the careful studies of experimental tumors suggest that under certain conditions normal appearing well differentiated glial cells may be induced to undergo neoplastic metamorphosis. And the more malignant forms of tumor appear to be due to anaplasia and not to failure of differentiation. These facts can also be established when a succession of biopsies of any one tumor is arranged in a series according to cell type (cf Kernohan) and in the study of the histopathology of tumors by whole brain sections which show the relation of the differentiated to the nondifferentiated parts (Scherer)

Table 132 INCIDENCE OF INTRACRANIAL AND INTRASPINAL TUMORS AT BOSTON CITY HOSPITAL 1900 1930

Total autopsies				10 92
Total number of tumors				1 [illegible] 8
Tumors of other organs			1 [illegible] 0	
Intracranial and intraspinal tumors			188 (1[illegible].7%)	
Gliomas		81 (43.1%)		
Pituitary adenomas		6 (3 [illegible]%)		
Sheath tumors		2 (11 [illegible])		
Meningioma	18			
Acoustic neuroma	4			
Metastatic tumors		29 (15.4%)		
Blood vessel tumors		6 (3.0%)		
Congenital tumors		8 (4.3%)		
Granulomas		19 (10.1%)		
Spinal cord tumors		4 ([illegible] 1%)		
Unclassified		13 (7.1%)		

INCIDENCE

Most of the available statistics on tumors of the central nervous system have been collected in special neurosurgical clinics and are somewhat misleading for they fail to reveal their natural incidence in an unselected population. The following figures compiled by Peer are therefore rather exceptional for they avoid this error of selection and represent the natural incidence of these tumors in post mortem material during the period 1900–1930 at a time when very little neurosurgery was being performed in the hospital from which they were taken (Boston City Hospital)

These data reveal that the central nervous system and its enveloping tissues are fruitful soil for tumor growth and further that the bulk of these tumors are gliomas metastatic tumors and meningiomas. The increasing rarity of gummas and tuberculomas noted in all pathologic material during the past two decades leads the authors to believe that far less than 10 per cent of these growths are now of granulomatous nature and the rising age of the population and the increasing frequency of all types of tumors would probably raise the figure for secondary tumors. Of the gliomas approximately half are glioblastoma multiforme and the remainder are divided between astrocytoma oligodendroglioma ependymoma medulloblastoma and undiagnosed gliomas. All statistics show the peak age incidence to be the fifth decade of life with a fairly symmetric curve which reflects the lessening incidence at the extremes of age—infancy and the senescent period. In children tumors of the posterior fossa (medulloblastomas ependymomas and gliomas) predominate in adults supratentorial tumors (glioblastomas meningiomas and metastatic carcinomas) are more frequent. Males appear to be more susceptible to intrinsic tumors of the brain (gliomas) than females the ratio being 2 1. The meningioma occurs more frequently in the elderly female

INTRACRANIAL TUMORS

Pathophysiology

The cranium according to the Monro Kellie law contains three elements—nervous tissue blood and cerebrospinal fluid the total bulk of which must always be constant. Any increase in the volume of the brain for example can take place only at the expense of one of the other elements and a diminished volume of brain is compensated by an increase in the amount of cerebrospinal fluid. The cerebrospinal fluid pressure while reflecting the volume of the intracranial mass is largely maintained by the pressure under which the blood is delivered to the skull. In profound shock the cerebrospinal fluid pressure falls and at death it is zero

When a tumor or other space occupying mass forms in the cranial cavity the volume of cerebrospinal fluid within the subarachnoid and ventricular spaces is reduced and the cerebrospinal fluid is displaced into the spinal and perioptic subarachnoid

sive vascular headaches etc may also begin early in the morning on first awakening The patient does not always complain of the pain even when it is present and often he betrays its existence by placing his hand on his forehead and looking distressed

The mechanism of the headache is not known In the majority of instances the intracranial pressure is normal during the first weeks when the headache is present and one can only attribute it to distortion or alteration of blood vessels in or around the tumor Later the headache appears to be related to rises in intracranial pressure The location of the headache bears some relation to the situation of the growth Tumors above the tentorium cause headache on the side of and in the vicinity of the tumor usually in the orbital frontal temporal or parietal regions Tumors in the posterior fossa usually cause ipsilateral retroauricular or occipital headache With elevated intracranial pressure bifrontal and bioccipital headache is the rule regardless of the location of the tumor

Vomiting appears in about one third of the patients with tumor syndromes of this type and usually accompanies the headache It is more frequent with tumors of the posterior fossa Some patients may vomit unexpectedly and forcibly without preceding nausea (projectile vomiting) but others suffer both nausea and great pain Usually the vomiting is not related to the ingestion of food often occurring before breakfast

No less frequent is the complaint of *giddiness* or *dizziness* As a rule it is not described with accuracy and consists of a more or less confused sensation in the head coupled with feelings of strangeness and insecurity when its position is altered As such it can be assigned little or no localizing value Its relationship to labyrinthine stasis or "choked ear" is difficult to verify The labyrinthine function in such cases is usually normal True rotational vertigo may also occur and usually signifies disease of the eighth nerve medulla or cerebellum

One or more generalized *convulsions* is the other major symptom which calls attention to the existence of cerebral tumor Their frequency in various statistical analyses is 20 to 50 per cent of all patients with cerebral tumors The onset of a seizure during adult years and the existence of a localizing aura are always suggestive of tumor The localizing significance of seizure patterns has already been discussed (see Chap 35) The seizures may occur once or many times and may precede other symptoms for as long as 10 or more years (in cases of astrocytoma or meningioma) The manner in which a cerebral tumor can cause a seizure is not known The majority of the tumors involve the cerebral cortex though a few cerebellar tumors will be accompanied in the late stages by a generalized seizure for a reason that usually cannot be determined

The management of patients who present any one of the afore mentioned symptoms requires brief discussion The physician is well advised whenever he encounters any clinical problem of this type to consider the possibility of a cerebral tumor in its early stages A careful inquiry should then be made concerning the rest of the symptoms of this complex In other words if either a recurrent headache of a type which the patient recognizes as different from his customary headaches or a seizure appearing for the first time has occurred there is indication for a careful review of the patient s general behavior In obtaining further data one must rely heavily on the observations of other members of the family A thorough neurologic examination with careful inspection of optic fundi a test of visual fields motor reflex, and sensory functions in the limbs alertness memory facility in language (speaking reading writing and understanding the spoken word) calculation tests of visuospatial orientation (see Chap 36) must follow Sooner or later other regional or localizing symptoms and signs will be discovered and it is only by repeated examinations that one will note the earliest stages of a hemiparesis aphasia visual field defect hemianesthesia etc (For the interpretation of these localizing symptoms and signs the reader is referred to Chaps 25 35 and 36) Unmistakable signs of increased intracranial pressure may become manifest and establish the diagnosis of tumor with reasonable certainty (see Astrocytoma below)

The necessity of performing confirmatory diagnostic tests will be realized sooner or later and the decision as to the appropriate time for doing them requires balanced clinical judgment Since many of the symptoms described above are in no way specific one should rely on repeated and thorough examinations and should not proceed too quickly to expensive and difficult diagnostic tests Watchful waiting without unduly alarming the patient is the best plan for a certain period As more of the clinical picture unfolds however there comes a time when x rays of the skull and chest (always done to help rule out metastatic carcinoma) lumbar puncture (for pressure cells protein and Wassermann) and localizing electroencephalogram should be made preferably by admitting the patient to a hospital Perimetry audiograms vestibular tests and psychometric tests are also helpful in the study of many of these patients Pneumoencephalography and carotid arteriography are reserved in most medical neurologic clinics for those in whom the total clinical syndrome is already strongly suggestive of tumor These procedures are too costly and hazardous to be used routinely in every tumor suspect

treatment of each pathologic entity must be considered separately This can be done in either of two ways—by taking up seriatim each of the special types of tumor i e following a scheme based on pathology with the clinical manifestations of each tumor type being added or by making a purely clinical approach presenting the common syndromes created by intracranial tumors and then offering only a few relevant points with respect to pathology The latter scheme is followed here

It may be said at the very outset that tumors of the brain may exist with hardly any symptoms Often only a slight deficiency in mental power a slowness in comprehension or a loss of capacity in sustaining continuous mental activity suggests any deviation from normal health Specific signs that would lead to a suspicion of any real cerebral disease may be wholly wanting In some patients on the other hand there is evidence of cerebral disease in the form of a seizure or some other symptom but the evidence is not clear enough to warrant the diagnosis of a cerebral tumor In a third group the existence of a new growth in the brain may be determined with much probability by the presence of signs of elevated intracranial pressure but there are no symptoms which warrant localization of the growth Lastly the symptoms may be so clear and definite as to make it probable not only that there is a new growth within the cranium but that it is located in one particular region In fact these localized growths may create unique tumor syndromes unlike those of any other disease

These are the plain facts of clinical observation in the further exposition of this subject therefore all intracranial tumors are considered in relation to the common clinical circumstances in which they are likely to be encountered as follows

1 The patient whose presenting symptom is either a decline in general mental ability or a seizure

2 The patient with unmistakable evidence of raised intracranial pressure

3 Specific intracranial tumor syndromes

The Patient with General Symptoms of Cerebral Disease or a Seizure as His Main Complaint In general practice or on the wards of the hospital these are the patients who give the most trouble in diagnosis and about whom decisions are often made with a great degree of uncertainty Their symptoms are general as a rule and not until some time has elapsed will signs of focal brain disease be added and when they do they are not always of accurate localizing value Altered psychic functions headache giddiness and seizures comprise the usual symptomatology in this group of patients

As pointed out by Knapp some *change in mental function* may be found in nearly every patient of this type but it may be necessary to obtain observations of a person who knows the patient intimately to learn of it A lack of power of persistent application to the tasks of the day an undue irritability emotional lability a peculiar inertia " faulty insight forgetfulness inability to retain impressions indifference to social practices lack of initiative and spontaneity all of which may pass for worry anxiety or depression are the usual symptoms Much of this behavior is accepted by the patient with forebearance and if he has any complaint it is of being weak tired dizzy (nonrotational) or queer in the head Inordinate drowsiness a remarkable equanimity and stoicism may be prominent findings These symptoms become more persistent and obtrusive with the passage of time Usually within a few weeks or months the drowsiness and mental dullness increase This curious inertia and lack of spontaneity then become even more conspicuous and are evident during the interview The patient seems strangely indifferent to the questions of the examiner A long pause precedes each reply and at times the patient may not bother to respond at all Or at the very moment when the examiner has decided that the patient has not heard the question and prepares to repeat it an appropriate sensible answer is given usually in relatively few words The responses are usually much more intelligent than would be expected from the torpid mental state There are in addition patients who are confused or demented (see Chap 36) The dullness and somnolence may gradually increase and finally end in coma

Mental symptoms of this type cannot be ascribed to disease in any particular part of the brain Wilson has expressed the opinion that tumors are most likely to be accompanied by intellectual disturbance when they interfere with large association fiber systems such as the corpus callosum inferior and superior longitudinal fasciculi etc he states that cortical growths are less likely to affect the mind The drowsiness torpor inertia lack of spontaneity and general restriction of the mental horizon are usually related to increased intracranial pressure and are unrelated to the site and nature of the lesion

The *headaches* in the tumor patient may vary exceedingly In some the pain is slight temporary and dull in character in others it may be severe and unendurable being either dull or sharp but as a rule transitory or intermittent If there are any characteristics of the headache they are its nocturnal occurrence its presence on first awakening and its deep nonpulsatile quality However these are not specific attributes since migraine hyperten

malignant degeneration and present as mixed astrocytomas and glioblastomas In 94 gliomas studied post mortem by Scherer of which 18 were astrocytomas all but 5 showed areas of glioblastoma multiforme This fact as well as the frequent finding of fiber forming astrocytes throughout the tumor (obviously tumor cells and not reacting astrocytes) has led Kernohan and his associates to conclude that the glioblastoma astroblastoma and astrocytoma are all derived from mature astrocytes which have undergone various degrees of anaplasia Thus the glioblastoma is an astrocytoma of grade 4 malignancy and the astroblastoma is of grade 2 or grade 3 malignancy The authors observations are for the most part in agreement with this opinion though one must admit the possibility that glial tumors of other cell types upon becoming anaplastic might occasionally give rise to a glioblastoma The astroblastomas fall between the astrocytoma and glioblastoma in both clinical and pathologic characteristics

The astrocytoma may cause trivial symptoms for a long period of time Seizures headaches and bizarre mental symptoms may be present for several years in a few instances more than 10 before the diagnosis is made The average survival period after the first symptom is 67 months in cerebral growths and 89 months in cerebellar ones The cystic astrocytoma of the cerebellum is particularly benign and some patients are alive and well as long as 20 years after part of the cyst was excised Here of course accuracy of the original diagnosis of neoplasm is always open to question The astrocytoma of the pons optic nerves and chiasm will be discussed in more detail later on in this chapter

OLIGODENDROCYTOMA The oligodendrocytoma is a relatively rare cerebral tumor (5 to 10 per cent of gliomas) and is usually slow in its rate of growth (average span of evolution is 66 months) It is generally a soft solid tumor rarely cystic or hemorrhagic and through its tendency to calcify (spherules and particles of calcium in microscopic sections) often casts a shadow in the roentgenogram of the skull Microscopically it is composed of small round cells with spherical nuclei and cytoplasm that stains poorly forming a halo around the nucleus Seizures are uncommon and generalized or focal cerebral symptoms may be present for a long time before the mass of the tumor declares its presence by increased intracranial pressure

EPENDYMOMA AND EPENDYMOBLASTOMA Although occasionally this tumor presents as a solitary mass in a cerebral hemisphere in adults presumably arising from the ependymal wall of the lateral ventricle its most distinctive form is a papillary growth filling the fourth ventricle of children It will be discussed further on p 1632

MENINGIOMA (ARACHNOIDAL FIBROBLASTOMA AND ENDOTHELIOMA) This is a benign tumor composed of specialized arachnoidal lining cells arising usually in places where there are arachnoidal villi Since these clusters of arachnoidal cells penetrate the dura in the vicinity of the venous sinuses they often appear to originate from the dura itself hence the old term "dural endothelioma Grossly the tumors are firm gray white lobulated bulbous or plaquelike masses which indent or compress but do not invade brain tissue Many of them are highly vascular In size they are variable some are only a centimeter or two in size and are turned up as incidental findings at autopsy Others usually those which have produced symptoms have attained a size of 3 to 4 cm or more The cellular composition permits easy identification The cells are of uniform type and have the peculiar disposition to encircle one another and to form characteristic whorls and psammoma bodies The common sites of these tumors are the olfactory groove tuberculum sellae parasagittal region Sylvian fissure cerebellopontine angle and spinal canal In as much as they lie on the surface of the brain in or next to the dura changes in the skull are frequent The skull may be eroded over the tumor and the diploic vessels which provide part of the blood supply of the tumor dilate and are unusually prominent in an x ray Or the tumor cells may invade the bone and stimulate osteoblastic activity as a consequence of which a bony bulge may be seen and felt or an endostosis is visualized on the inner table of the skull in an x ray The meningioma must be listed with metastatic carcinoma and the true cholesteatoma as the three tumors most likely to cause a visible cranial boss in relation to cerebral symptoms (*benign exostoses are neurologically asymptomatic*) Offering a broad vascular meningeal surface as they do these tumors often elevate the protein of the cerebrospinal fluid Their striking vascularity accounts for the characteristic blush seen in arteriograms and the excessive permeability of the vessels as well as the superficial location of the tumors make them ideal subjects for localization with radioactive isotopes The displacement without invasion of cerebral tissue probably explains the interruption locally of normal alpha frequencies in the EEG with sharp waves or theta waves in contrast to the delta waves so often found in infiltrative gliomas Multiple meningiomas may be found particularly in cases of neurofibromatosis

These tumors may be found at any age but are more frequent in advanced years especially in women Their slow growth is reflected in the long duration of symptoms in many cases and their indentation of cerebral cortex explains the high incidence of focal convulsions Aside from the general cerebral disorder and seizures those tumors

One proceeds on the basic assumptions that tumor symptoms and signs are progressive and that the treatment of tumors of the brain may proceed satisfactorily from the point at which diagnosis becomes fairly obvious from the clinical facts alone Experience teaches that little gain comes from attempting early diagnosis and early operation before signs are well established This point will be further discussed under Treatment

Tumors Which Tend to Produce General Cerebral Symptoms or Seizures The following tumors are most likely to produce initial convulsions or a vague syndrome of headache giddiness vomiting dull or stuporous state and psychic changes glioblastoma multiforme astrocytoma oligodendroglioma metastatic carcinoma meningioma and primary reticulum cell sarcoma of the cerebrum

GLIOBLASTOMA MULTIFORME In all statistic analyses of surgical and post mortem material glioblastoma multiforme is responsible for more than 25 per cent of intracranial gliomas and for more than 90 per cent of gliomas of the cerebral hemispheres in adults Approximately 20 to 30 per cent of the cerebral tumors are bilateral occupy more than one lobe of a hemisphere or show multicentric foci of growth Although predominantly cerebral in location similar tumors may be observed in the brain stem cerebellum or spinal cord The peak incidence is in middle adult life but no age group is spared

The glioblastoma is a highly malignant tumor which infiltrates the brain extensively and may attain enormous size It may extend to the meningeal surface or the ventricular wall which probably accounts for the elevation of protein (often over 100 mg per cent) in many cases and sometimes a pleocytosis of 10 to 100 or more cells mostly lymphocytes The tumor has a variegated appearance being a mottled gray red orange or brown depending on the degree of necrosis and whether hemorrhage is recent or old It is highly vascular and in an arteriogram one can often see a network of abnormal vessels mistaken at times for a hemangioma and the displacement of normal vessels which may result from any mass lesion Some part of one lateral ventricle is often distorted and both lateral and third ventricles are displaced contralaterally which may be demonstrated by pneumoencephalography or ventriculography The vessels in the tumor are excessively permeable to fluorescein P^{32} radioactive arsenic etc which is the basis for radioactive scanning techniques Calcification and cavity formation are not prominent The characteristic microscopic pathologic findings are great cellularity with pleomorphism of cells and hyperchromatism of nuclei identifiable astrocytes with fibrils in combination with astroblasts tumor giant cells and cells in mitosis a curious neoplastic proliferation of the cells of small vessels (adventitial and endothelial) necrosis pseudopalisading of viable cells hemorrhage and thrombosis of vessels Temporal lobe–tentorial herniation midbrain compression midbrain and pontine hemorrhages and increased intracranial pressure are usually the immediate causes of death At autopsy the tumor is often seen spreading along cerebrospinal fluid pathways (seedings around spinal cord and cauda equina) but metastasis outside the craniovertebral cavity is almost unheard of except postoperatively when dura scalp and draining cervical nodes are invaded

Clinically the diffuse cerebral symptoms and seizures (present in 30 to 40 per cent of cases) usually give way to a more definite frontal temporal parietooccipital or callosal syndrome in a few weeks or months Seldom however do the symptoms and signs point to one lobe and often one is satisfied to be able to specify the region of the hemisphere which is involved When the corpus callosum is invaded as it so often is the so called callosal syndrome (apathy drowsiness forgetfulness apractic and agnostic disturbance) may precede or follow other lateralizing signs Increased intracranial pressure usually follows the other neurologic signs There are no other important clinical abnormalities The sedimentation rate white cell count and hemoglobin remain normal Survival for more than a few months or a year after operation is exceptional and should lead one to question the accuracy of histologic diagnosis

ASTROCYTOMA The astrocytoma may occur anywhere in the brain or spinal cord Favored sites are cerebrum cerebellum thalamus optic chiasm and pons It is a slowly growing tumor of infiltrative character with a marked tendency to undergo some type of degeneration with the formation of large cavities or cysts In some instances much of the tumor may be composed of a cyst surrounded by a thin border of astrocytic tissue and the only sizable mass of tumor tissue may be a mural nodule Others of these tumors are noncystic grayish white firm and relatively avascular almost indistinguishable from normal white matter with which they may merge imperceptibly Calcium deposits may occur in parts of the tumor and may be seen in a plain x ray of the skull The cerebrospinal fluid is acellular the only abnormality being the increased pressure and elevated protein in some cases The tumor by its mass may distort the lateral and third ventricles (seen in pneumoencephalogram or ventriculogram) and may be seen to displace the anterior and middle cerebral arteries in a carotid arteriogram Microscopically the tumor tissue is composed of well-differentiated astrocytes of fibrillary protoplasmic or transitional type

The majority of cerebral astrocytomas undergo

upon awakening vomiting that may or may not be unexpected and projectile mental torpor and papilledema (see Chap 31)] when first seen The physician confronted with this clinical problem is forced to take immediate action for the condition is potentially dangerous A critical rise in intracranial hypertension may occur at any time and result in coma respiratory arrest and death Admission to a hospital with a neurosurgical service is therefore usually urgent Nevertheless all the medical aspects of the patient s problem should first be worked out

Three questions demand immediate answers (1) Does the patient have a space occupying intracranial lesion? (2) Where in the cranial cavity is it situated? (3) What is its nature? With respect to the first question it is well to keep in mind that a number of medical conditions may simulate an intracranial growth that causes only the general symptoms of increased intracranial pressure These are (1) "pseudotumor cerebri (2) hypertensive encephalopathy (3) chronic pulmonary disease with hypercapnia and hypoxia (4) chronic adhesive arachnoiditis and/or aqueductal stenosis (5) thrombosis of cerebral veins and dural sinuses (6) Addison s disease with encephalopathy or hypoparathyroidism with papilledema Several of these conditions have been discussed elsewhere in this book and it is sufficient to mention them briefly others have not been considered before and will be discussed in detail

Pseudotumor Syndromes In the condition of *pseudotumor cerebri* (meningeal hydrops) the patient more often than not a young woman complains of headaches of some weeks standing and when first examined is found to have papilledema or choked disk with slightly constricted visual fields and enlarged blind spots Other neurologic signs with the occasional exception of a vague dizziness diplopia due to a slight abducens weakness or paresthesias of some part of the body are conspicuously absent and the patient appears remarkably bright and well The cerebrospinal fluid is acellular with normal protein content and small or normal sized ventricles in a ventriculogram With daily then biweekly then weekly lumbar punctures to lower the cerebrospinal fluid pressure most of the patients gradually recover over a period of weeks to months Extremely high cerebrospinal fluid pressure with episodes of cloudy vision (obscurations) may herald the onset of blindness and require a right subtemporal decompression as an emergency measure The cause of the condition is unknown Extreme hypertension (diastolic pressures of 120 mm or over) retinal arteriolar changes with hemorrhages and exudates in the periphery of the optic fundi signs of renal disease and headache convulsions confusion stupor or coma are the basis of the diagnosis of *hypertensive encephalopathy* (see p 1600) *Chronic emphysema or other lung disease with cyanosis dyspnea cough signs of cor pulmonale with right sided congestive heart failure and secondary polycythemia* may be attended by bilateral papilledema elevated cerebrospinal fluid pressure high venous pressure severe headache drowsiness stupor or coma and a peculiar lapse in the posture of the outstretched limbs and other contracted skeletal muscles (flapping movements or asterixis similar to the flap in impending liver coma) The finding of an elevated carbon dioxide-combining power and diminished arterial oxygen concentration substantiate the diagnosis *Chronic adhesive arachnoiditis* due to chronic fibrosing meningeal diseases such as syphilis postspinal anesthesia arachnoiditis and cryptogenic meningeal diseases may be attended by headache papilledema seizures blindness paraplegia or quadriplegia The cerebrospinal fluid protein may be normal or elevated with or without a "dynamic block and the lateral and third ventricles are enlarged in the ventriculogram Syphilis and the other chronic meningitides may also cause *aqueductal stenosis* owing to a proliferative gliotic ependymitis with enlargement *of the lateral and third ventricles* (see Chap 253) *Thrombosis of the jugular veins and of the lateral and posterior parts of the superior sagittal sinus* may result in increased intracranial pressure with otherwise normal cerebrospinal fluid and small ventricles (see Chap 146) Several cases of unexplained papilledema with headache drowsiness and confusion and elevated cerebrospinal fluid pressure have been observed in conjunction with *Addison s disease* (Jefferson) and also in rare cases of hypoparathyroidism The mechanism is not known *Retrobulbar neuritis of demyelinative type* if it extends to the optic nerve head may cause a papillitis with elevation and edema of the optic disk and even hemorrhages around the disk There is invariably an early development of a marked impairment of vision and large central scotomas The prominent visual change and the absence of clinical and laboratory evidence of increased intracranial pressure distinguish this condition from true papilledema and also from pseudopapilledema (spurious papilledema) and tortuosity of retinal veins—a normal ophthalmoscopic picture in some patients especially those with marked hyperopia Severe anemia may also cause hemorrhages exudates and a *suspicion of papilledema* which may at times be confused with the retinal picture of neoplasm

False Localizing Signs" If the clinical findings permit the exclusion of the afore mentioned conditions there is reasonable certainty that the patient has an intracranial growth The problem then is to search for signs which will localize the lesion In doing this several pitfalls must be avoided One

which occupy special locations create unique syndromes Some of these will be discussed later starting on p 1634

METASTATIC CARCINOMA Of the secondary tumors of the brain only metastatic carcinoma will be discussed here because the other tumors that metastasize to the brain are decidedly rare Carcinomas reach the brain by hematogenous spread Probably 35 to 40 per cent come from the lung and approximately 15 per cent each from the breast gastrointestinal tract (usually colon or rectum) and kidney Stomach melanotic carcinoma of the skin gallbladder liver thyroid testicle uterus ovary etc account for the remainder no one of them usually being responsible for more than 3 or 4 per cent of secondary tumors of the brain Carcinoma of the prostate esophagus oropharynx or skin (except for melanocarcinoma) rarely if ever is disseminated in the brain In more than 75 per cent of cases the metastases are multiple and are scattered through both the cerebrum and cerebellum often near the surface and involving white matter cortex and meninges The hypernephroma and thyroid carcinoma have a greater tendency to form solitary metastases than other tumors and as with the chorionepithelioma and some lung tumors the metastases are likely to be hemorrhagic The tumor tissue generally has all the gross and microscopic features of any carcinomatous implant and excites rather little glial reaction but much edema

The usual clinical picture in metastatic carcinoma of the brain has already been described under Glioblastoma Multiforme A number of rather striking clinical neurologic syndromes also occur One that is particularly difficult to diagnose is a widespread *carcinomatous meningoencephalopathy* with headache nervousness depressed mood trembling mental confusion and forgetfulness the whole picture looking very much like that of general paresis Carcinomatosis of the cerebellum with headache dizziness and ataxia the ataxia being brought out only by having the patient walk is another difficult condition to diagnose during life Such patients may be regarded as hysterical until sudden death due to a cerebellar pressure cone terminates the illness Here the metastases are more or less limited to the midline structures of the cerebellum Symptoms and signs referable to one or several cranial and spinal nerve roots may be combined with headache and confusion in widespread *carcinomatosis of the craniospinal meninges* (carcinomatous meningitis) Usually the cerebrospinal fluid contains a few white blood cells (lymphocytes) and an elevated protein Tumor cells can often be identified in Papanicolaou stains of cerebrospinal fluid sediment and if many are present in the meninges the sugar values may be subnormal even as low as 0

When the syndromes due to these several varieties of metastatic tumor are fully developed diagnosis is relatively easy If only headache and vomiting are present a common error is to explain these symptoms on a psychologic basis One should make a psychiatric diagnosis only if the patient has the standard symptoms of the mental illnesses (see pp 361 362) A lumbar puncture chest x ray (positive in 75 per cent of cases of metastatic tumor of brain) and other x rays (gastrointestinal series barium enema and pyelograms if symptoms point to these organs) are advisable The metabolic neurologic syndromes which accompany carcinoma but which are not due to tumor invasion of the central nervous system (multiple neuropathy especially with carcinoma of the lung) polymyositis and spinocerebellar degeneration (ovarian and other carcinomas) should also be kept in mind

TUMORS OF INFECTIVE ORIGIN (GRANULOMAS AND PARASITIC CYSTS) Tuberculoma is much less frequent in the United States than it was 20 years ago and gumma has become almost nonexistent In fact a patient with serologic syphilis and a positive Wassermann reaction of the cerebrospinal fluid has a greater chance of having two diseases a cerebral tumor and asymptomatic neurosyphilis than a gumma The tuberculoma may occur in any part of the brain but in children it is more likely to develop in the posterior fossa i e in the cerebellum or brain stem than in the cerebrum Often there are a small number of cells and an increased protein content in the cerebrospinal fluid because the lesion frequently lies contiguous to the meninges and it may at any time give rise to a tuberculous meningitis with typical cerebrospinal fluid formula (50 to 300 cells increased protein decreased sugar and chloride content)

In South America tuberculoma and gumma are much more frequent and one can usually depend on evidence of disease in other parts of the body especially the lungs and characteristic changes in the cerebrospinal fluid (see Chap 31) to indicate the nature of the lesion In addition cysticercus cellulosae and hydatid cysts are common lesions and should always be suspected when seizures increased intracranial pressure or diffuse cerebral symptoms develop in the adult X rays of the skull and skeletal muscles (e g thigh) may reveal characteristic calcific deposits in cysticercosis Torula and other fungous granulomas and *Schistosoma japonicum* infection may also present as space occupying cerebral lesions (see pp 1134 1139 985)

Patients with Unmistakable Signs of Increased Intracranial Pressure When First Seen A certain number of patients show all the characteristic symptoms and signs of increased intracranial pressure [periodic bifrontal and bioccipital headaches which awaken the patient during the night or are present

duct of Sylvius Often it extends anteriorly into the third ventricle and may then compress the hypo thalamus Microscopically it is composed of large spherical epithelial cells (much like those of a semi noma) separated by a network of reticular con nective tissue which contains many lymphocytes The gliomas have the usual morphology of an astro cytoma of varying degrees of malignancy Children adolescents and young adults either male or fe male may be affected In some cases the clinical syndrome consists solely of symptoms and signs of increased intracranial pressure and the diagnosis can be made only by a ventriculogram which reveals the tumor The most characteristic symptom however is an inability to look upward (Parinaud s syn drome) with slightly dilated pupils which react on accommodation but not to light Sometimes ataxia of the limbs choreatic movements or spastic weak ness appears in the later stages of the illness A Torkildsen ventriculo-cisterna magna shunt of cere brospinal fluid and x ray therapy have been remark ably successful in controlling the symptoms At tempts at surgical removal of the tumor have usu ally proved fatal

COLLOID (PARAPHYSEAL) CYST OF THE THIRD VEN TRICLE This is a papillomatous structure always situated in the anterior extremity of the third ven tricle between the interventricular foramens and attached to the roof of the ventricle Usually it is about a centimeter in diameter is oval or round with a smooth external surface and is filled with a glairy colloid material The wall is composed of a layer of epithelial cells surrounded by a capsule of fibrous connective tissue These benign cysts may exist for long periods of time they produce neuro logic symptoms by blocking the third ventricle and causing an obstructive hydrocephalus This tumor should be suspected when the following clinical syndromes are found dementia with or without headache intermittent severe bifrontal bioccipital headaches sometimes modified by posture (ball valve obstruction of the third ventricle) crises of headache with obtundation bilateral paresthesias dim vision and weakness of legs with sudden falls

CRANIOPHARYNGIOMA (SUPRASELLAR OR RATHKE POUCH CYST HYPOPHYSEAL DUCT TUMORS ADAMAN TINOMAS AMELOBLASTOMAS) This is a benign con genital or rest cell tumor By the time it has grown to a diameter of 3 to 4 cm it is almost always cystic Usually it lies above the sella turcica de pressing the optic chiasm and extending up into the third ventricle Less often it is subdiaphragmatic i e within the sella where it compresses the pitui tary body erodes one part of the wall of the sella or a clinoid process but seldom balloons the sella like a pituitary adenoma. The tumor is oval round or lobulated and has a smooth surface The wall of the cyst and the solid parts of the tumor consist of cords and whorls of epithelial cells often with inter cellular bridges and keratohyalin separated by a loose network of stellate cells The cyst contains dark albuminous fluid and cholesterol crystals Cal cium deposits are found in nearly all of them and can be seen in plain x rays of the suprasellar region in about 40 per cent of cases The sella beneath the tumor tends to be flattened and enlarged This is more often a tumor of children than of adults but patients of all ages may be seen with it In chil dren adiposity delayed or infantile physical and sexual development (Froehlich s syndrome or Lorain syndrome—cf Chap 253) headaches vomit ing dim vision with chiasmal field defects (see p 269) optic atrophy or papilledema comprise the clinical picture In adults waning libido amen orrhea slight spastic weakness of the legs head ache without papilledema and mental dullness and confusion are often found Later drowsiness dia betes insipidus and disturbances of temperature regulation may occur indicating hypothalamic in volvement (see p 268)

In the differential diagnosis of these several tu mor syndromes a careful clinical analysis is often more important than laboratory procedures Arteri ography and electroencephalography are not so helpful as in cerebral tumors The one test which though somewhat hazardous is likely to give the most useful information is a ventriculogram or a combined ventriculogram pneumoencephalogram

Tumors of the Posterior Fossa and Third Ven tricle in Infancy and Early Childhood Any discus sion of tumors of the brain would be incomplete if some reference were not made to intracranial tumors of infancy and childhood for they often create clinical problems of a special type Fully two thirds of tumors before the age of puberty are medulloblastomas ependymomas cerebellar astro cytomas and pontine gliomas are situated in the posterior fossa and produce increased intracranial pressure Hence this brief digression is appropriate at this point in the general exposition

As stated in Chap 253 in the section on congenital hydrocephalus the cranial sutures do not close until about the time of puberty and an elevation of intracranial pressure especially if it occurs in the first months and years of life results in separation of sutures and enlargement of the head This is evident by inspection by head meas urement and in x rays and it is also demonstrated by finger percussion of the parietal eminence of the skull which produces a peculiar sound as though a cracked cup or bowl were being tapped (Macewen s sign) The separation of sutures by enlarging the intracranial cavity permits temporary restitution of intracranial pressure and amelioration of symptoms Papilledema does not develop if the head enlarges

common source of error is to place undue reliance on a sign which proves to have no localizing value whatsoever With experience in this field one comes to distrust any symptom or sign which develops late after headache and increased intracranial pressure have been established for it often turns out to be a "false localizing sign" Under these circumstances drowsiness slowness in response inattentiveness and emotional blunting can be found as often with cerebellar as with cerebral growths Unilateral or bilateral abducens palsy is another common false localizing sign (Collier) and reference has already been made to the drooping eyelid dilated pupil ipsilateral hemiparesis and bilateral Babinski signs and coma in temporal lobe herniation Jacksonian and generalized seizures and ipsilateral or bilateral pyramidal signs may be observed in the advanced stages of a cerebellar tumor On the other hand relatively slight focal signs that may be easily overlooked are sometimes the only clues as to the localization of the tumor Examples are ataxia of gait (but not of limbs) and head tilt in cerebellar tumors paralysis of upward gaze with the Argyll Robertson pupillary phenomenon in pinealomas pale optic disks and chiasmal field defects in craniopharyngiomas homonymous visual inattentiveness and sensory extinction (see pp 279 and 342) in posterior cerebral tumors and a facial asymmetry in emotional expression in frontal tumors

Tumors Which Tend to Produce Elevated Intracranial Pressure without Conspicuous Localizing Signs The tumors most likely to cause increased intracranial pressure with few or no focal or lateralizing signs are medulloblastoma ependymoma of the fourth ventricle hemangioblastoma pinealoma colloid cysts of the third ventricle gliomas of tegmentum of the midbrain blocking the aqueduct and craniopharyngioma In addition in many of the cerebral gliomas discussed above particularly those of the corpus callosum and frontal lobes increased intracranial pressure may precede focal cerebral signs

MEDULLOBLASTOMA This is a rapidly growing tumor which arises in the posterior part of the vermis of children The midline part of the cerebellum may be invaded and completely destroyed The tumor also fills the fourth ventricle and compresses the medulla The tonsils of the cerebellum are forced down into the cervical spinal canal (cerebellar pressure cone) in fatal cases Seedings of the tumor may be seen on the walls of the third and lateral ventricles on the meningeal surfaces of the brain and around the spinal cord The tumor is solid reddish gray in color and poorly demarcated from the adjacent brain tissue It is very cellular and the cells are small closely packed with little cytoplasm many mitoses scant stroma and a tendency to form clusters or pseudorosettes As already stated these cells resemble the indifferent cells which Schaper described in the chick embryo and are thought to be capable of differentiation into either glial cells or neuroblasts Bailey and Cushing introduced the name *medulloblastoma* in 1925 Although medulloblasts as such have not been described in the fetal or adult human brain and the cell type is not known for certain the term is retained if for no other reason than its familiarity In adults a somewhat similar neuroblastoma of less malignant character may arise in the cerebral hemisphere

The clinical picture is distinctive Typically the patient a child of five to ten years becomes listless vomits repeatedly and has a morning headache The first diagnosis which suggests itself may be gastrointestinal disease or abdominal migraine Soon however a stumbling gait frequent falls and a squint lead to a neurologic examination and the discovery of papilledema Ataxia of the limbs may be absent at all times (cf Chap 26 on the syndrome of flocculonodular lobe) Decerebrate attacks (tonic cerebellar fits) may occur in the late stages of the disease The tumor is highly radiosensitive and surgery with x ray treatment may prolong life for several years

EPENDYMOMA AND PAPILLOMA OF THE FOURTH VENTRICLE This tumor also arises from the walls of the fourth ventricle in children It is a firm whitish lobulated growth composed of small cells arranged in the form of small rosettes around vessels or central clear areas and containing blepharoplasts in their cytoplasm Mitoses are absent if present they mark the tumor as an ependymoblastoma The clinical syndrome is much like that of the medulloblastoma except for the absence of ataxia of gait The tumor is not very sensitive to x ray and surgical removal offers the only hope of survival The papilloma or papillary adenocarcinoma of the choroid plexus of the fourth ventricle gives rise to a similar syndrome

HEMANGIOBLASTOMA OF THE CEREBELLUM The disease of Lindau was described in Chap 253 Dizziness ataxia of gait or of the limbs on one side symptoms and signs of increased intracranial pressure and in some instances a retinal angioma (von Hippel's disease) and polycythemia constitute the neurologic syndrome Familial incidence is well known Craniotomy with opening of the cerebellar cyst and excision of the mural hemangioblastomatous nodule may be curative

PINEALOMA This may be either a terotoma or a glioma of the pineal gland The teratoma is a firm discrete noninvasive mass which usually reaches 3 to 4 cm in greatest diameter It compresses the superior colliculi and sometimes the superior surface of the cerebellum with narrowing of the aque

ternal auditory meatus and obliteration of the lateral recess of the fourth ventricle in a pneumoencephalogram must be depended upon for diagnosis Dementia may later be the presenting syndrome and the deaf ear may be overlooked Unilateral cerebellar ataxia and dizziness may predominate and definite signs of involvement of the fifth seventh and eighth cranial nerves may not be found The treatment is surgical excision

The *trigeminal* or *gasserian ganglion neurinoma* and *meningioma* of the *cerebellopontine angle* may be indistinguishable from an acoustic neurinoma They should always be considered if early tinnitus and deafness and an unresponsive labyrinth ("dead labyrinth") are not the initial symptoms of the cerebellopontine angle syndrome A true *cholesteatoma of the temporal bone* may simulate this clinical picture but usually the facial weakness is early and severe the ear is deaf and labyrinthine function is absent whereas the other cranial nerve signs cerebellar ataxia and increased intracranial pressure are absent The *tumor of the glomus jugulare* (a flat ovoid body found in the adventitia of the jugular bulb immediately below the floor of the middle ear and near the ramus tympanicus of the ninth cranial nerve) may like the acoustic neurofibroma basal meningioma metastatic cancer syphilitic meningitis neurofibroma of other cranial nerves and vascular malformation cause unilateral lower cranial nerve palsies (see p 291) It is a purplish red highly vascular tumor composed of large epithelioid cells in an alveolar pattern and an abundant capillary network Partial deafness facial palsy dysphagia and unilateral atrophy of the tongue combined with a vascular polyp in the auditory meatus and a palpable mass below and anterior to the mastoid eminence often with a bruit comprise the syndrome The jugular foramen is eroded (visible by x ray) and the cerebrospinal fluid protein may be elevated Women are affected more than men and the peak incidence is during middle adult life The tumor grows slowly over a period of many years sometimes 10 or more The treatment is x ray radiation

THE PITUITARY ADENOMAS These tumors which are so common particularly in late adult life often are discovered when a patient begins to complain of a visual disturbance A unilateral or bilateral temporal hemianopia progressing to blindness with optic atrophy is the usual finding and with x ray evidence of an expanded sella turcica leads to a diagnosis of pituitary adenoma As the growth enlarges and extends laterally an oculomotor palsy is occasionally seen and large suprasellar extensions may involve the hypothalamus or temporal lobe If there are signs of acromegaly one may assume that an eosinophilic adenoma is present if not and signs of pituitary insufficiency are present (amenorrhea without hot flashes" sexual impotence etc—cf Chap 62) there is usually a chromophobe adenoma Basophilic adenomas one of the causes of Cushing s syndrome rarely if ever produce enlargement of the sella or visual symptoms The diagnosis is made from the endocrine picture (see Chap 62) The cerebrospinal fluid is usually under normal pressure and protein is elevated only in exceptional cases Other tumors may rarely expand the sella (craniopharyngioma) and there are also rather wide normal variations in its size Hence the diagnosis of pituitary adenoma should not be made because of minor enlargements in the absence of neighborhood neurologic signs In doubtful cases a pneumoencephalogram permits visualization of the suprasellar extension of the tumor Treatment is x ray radiation and if vision is threatened despite x ray therapy either transnasal or transfrontal surgical excision

MENINGIOMA OF THE SELLAR TUBERCLE This tumor arises from the region of tuberculum sellae and as it grows it lifts the optic chiasm upward and backward The optic nerves become stretched and separated With further increases in size it may expand anteriorly compressing the olfactory bulbs or posteriorly compressing the hypothalamus When the tumor is small the only symptom is bitemporal hemianopia later blindness with optic atrophy anosmia mental deterioration hemiparesis uncinate seizures oculomotor palsy and amenorrhea are added The diagnosis is made when a middle aged person is found to have a bitemporal hemianopia normal sized sella and no signs of hypothalamic or pituitary involvement Saccular aneurysm of the carotid artery and rarely craniopharyngioma extrasellar pituitary adenoma and Boeck s sarcoid may be confused with it The treatment is surgical excision

MENINGIOMA OF THE SPHENOID RIDGE This tumor arises from arachnoid cap cells over the lesser wing of the sphenoidal bone As it increases in size it may expand medially to encroach on structures in the wall of the cavernous sinus anteriorly to invade the orbit or laterally to erode or invade the temporal bone Most prominent among the symptoms are a slowly developing unilateral exophthalmos slight bulging of the bone in the temporal region and roentgenologic evidence of thickening or erosion of the lesser wing of the sphenoid bone Variants of the clinical syndrome include oculomotor palsy or syndrome of Foix (cf p 291) blindness in one eye with optic atrophy anosmia (and sometimes the Kennedy syndrome—see below) mental changes uncinate fits and increased intracranial pressure Sarcomas arising from the skull bones metastatic carcinoma orbitoethmoidal osteoma tu

The cardinal symptoms of a posterior fossa tumor in an infant or small child are different from those of the adult They consist of weakness vomiting and unsteadiness of gait These symptoms may fluctuate in severity tending to subside temporarily with further separation of sutures The vomiting may be prominent and occur at any time of day Often it is not preceded by nausea An erroneous diagnosis of cyclic vomiting or vomiting due to an emotional disturbance may be made Unlike vomiting due to intraabdominal disease this vomiting is not accompanied by abdominal pain Weakness and listlessness are also present but are more difficult to interpret Headache is seldom a complaint and seizures are rare

In tumors of the vermis of the cerebellum (medulloblastoma) the ataxia of gait and disinclination to walk (see Chap 26 on the vermis syndrome) without evident incoordination of the movements of arms or legs can usually be demonstrated by careful observation In astrocytoma or hemangioblastoma of one cerebellar hemisphere the ipsilateral arm and leg are ataxic (see Chap 26 on the syndrome of neocerebellum) and a nystagmus which is much coarser on looking to the side of the lesion than to the opposite side is present Also the head is often tilted with tumor of the cerebellar hemisphere the ear on the side of the tumor being brought towards the shoulder The ipsilateral arm is hypotonic and swings less than the contralateral one in walking General hypotonia and bilateral extensor plantar reflexes are late signs and are of less value in localization

These cerebellar signs when added to the general picture described above regardless of whether or not papilledema is present point to the posterior fossa as the site of a tumor More difficult to diagnose are the patients with only signs of hydrocephalus This condition may come about with a medulloblastoma arising in the upper vermis and filling the fourth ventricle or with an ependymoma arising from either the roof or the floor of the fourth ventricle Occasionally a craniopharyngioma may cause only hydrocephalus but then a peculiar docility an appearance of maturity due to greater interest in mental than physical activities and a retardation of growth may be helpful signs in identifying a lesion within the walls of the third ventricle

In later childhood separation of sutures and head enlargement are slight and headache and papilledema are the common signs of increased intracranial pressure just as in the adult

Patients with Symptoms and Signs of a Slowly Progressive Lesion in a Particular Region of the Cranial Cavity In this condition general cerebral symptoms and the signs of increased intracranial pressure occur late or not at all The physician arrives at the correct diagnosis by being able to make an anatomic or regional diagnosis from a set of neurologic findings and by reasoning that the etiology must be neoplastic because of the slowly progressive nature of the illness Special x rays of the skull cerebrospinal fluid examination and depending on the location of the disease either pneumoencephalography or arteriography will usually confirm the clinical impression

The following tumors produce unique syndromes usually diagnostic of a special type of tumor

ACOUSTIC NEUROFIBROMA OR NEURINOMA This slowly growing benign tumor may occur as a solitary lesion or as a part of the syndrome of neurofibromatosis Grossly by the time of operation the tumor has usually attained a size of 4 to 6 cm in diameter It arises from the extramedullary part of the eighth cranial nerve usually within the internal auditory meatus where the intracranial part of the nerve first acquires the histologic character of a peripheral nerve i e with Schwann cells and fibroblasts The space in which it lies is the cerebellopontine angle i e between the cerebellum pons and medulla posteriorly the petrous pyramid anteriorly and the tentorium above The internal auditory meatus is usually enlarged (visible in x rays) the middle cerebellar peduncle and the anterolateral part of the cerebellum are depressed and the trigeminal facial glossopharyngeal and vagus nerves are displaced and stretched over the surface of the growth The fourth ventricle is deformed displaced and narrowed (visible in a pneumoencephalogram) and there is hydrocephalic enlargement of the aqueduct and of the third and lateral ventricles in the late stages The tumor is vascular and the surrounding cerebrospinal fluid has a high protein content (cerebrospinal fluid protein of 300 mg per cent or over is not infrequent) The microscopic picture is that of a typical neurofibroma (axis cylinders mixed with masses of fibrous connective tissue in interlacing strands palisaded nuclei and mononuclear giant cells without mitoses) The typical clinical syndrome which usually occurs in adult men or women is tinnitus deafness and rotational vertigo [seldom in discrete attacks as in Meniere s syndrome (see p 273)] of several years standing followed by stiff neck and postauricular or suboccipital pain spasms and twitching or slight weakness of the face paresthesias or pain in the face dysphonia and dysphagia and homolateral cerebellar ataxia of the arm and leg Headache vomiting and choked disk are late findings Variations of this syndrome are numerous Early in its development only progressive deafness tinnitus and vague vertigo may be present and the abnormal audiogram impaired vestibular function elevated cerebrospinal fluid protein widened in

factors As a general rule unless an operation is performed almost all intracranial tumors end fatally Death in most instances is preceded by a critical rise in intracranial pressure and tentorial or foramen magnum herniation The more malignant tumors such as the glioblastoma multiforme medulloblastoma and metastatic carcinoma end fatally within a year as a rule whereas the slowly growing meningiomas and astrocytomas often permit survival for many years

The prospects for recovery after surgery depend largely upon the type of tumor With meningiomas and acoustic neurofibromas if completely excised there may be a complete cure In gliomas the outlook is more bleak Cure is rare for seldom can complete excision be accomplished Nevertheless with the slow growing gliomas partial excision the marsupialization of a cyst the relief of increased intracranial pressure may lead to improvement and resumption of a useful life for many years With metastatic growths the outlook is dismal though if there are no metastases in other organs and the cerebral deposit appears to be solitary operation has occasionally resulted in temporary recovery for a few months or a year or two

Treatment

The treatment of primary intracranial tumors is surgical removal Unless the patient is old or suffers some other disease which threatens to take his life within a few months the brain tumor should be exposed by craniotomy and biopsied This craniotomy which usually carries a mortality rate of 2 to 5 per cent should be undertaken only when the diagnosis of an intracranial space occupying lesion is clearly established by clinical symptoms and signs and confirmed by one or more special diagnostic procedures The latter should be kept at a minimum arteriography and ventriculography are in themselves hazardous particularly if done when intracranial pressure is high and they add to the mortality from craniotomy

The premium on early diagnosis is not so great as in tumors elsewhere in the body In the vast majority of patients there is little prospect that an early diagnosis and operation will improve the surgical result or effect a cure The benign surface tumors grow so slowly that one can usually temporize for weeks or months if diagnosis is uncertain without significantly worsening the surgical outcome providing of course that the operation is not delayed until high intracranial pressure has developed If the tumor is a glioma the prospect of complete eradication even with early operation is almost nil hence little is lost by waiting a few weeks or months providing the patient is not permitted to become comatose before being transferred to the neurosurgeon in which instance the chances of surviving the operative procedure are poor By waiting for the clinical syndrome to evolve one avoids diagnostic errors (confusion of tumors with other diseases)

The physician s responsibilities in this field of intracranial tumors are (1) diagnosis—he must separate the tumor cases from all the others which pass through his hands (2) exclusion of the possibility that the intracranial mass is part of a general disease which would contraindicate surgery i e metastatic carcinoma syphilis tuberculosis parasitic infections etc (3) exclusion of the several pseudotumor syndromes (4) maintenance of the patient in the best possible condition until surgery can be undertaken (fluids electrolytes etc) (5) assisting the surgeon in the postoperative medical management Dehydration i e use of hypertonic solutions [$MgSO_4$ by mouth or rectally or 50 per cent sucrose by vein (cf p 1618)] may be of help as a palliative measure in tiding the patient over a bout of intracranial hypertension In inoperable cases the objectives are to maintain the morale of the family and patient as long as possible and to provide intelligent supportive therapy

In general although the results of therapy are frequently disappointing there are always the few dramatic successes that serve as a perpetual stimulus to the physician and so it is always with the next patient that he hopes to achieve a cure

SPINAL CORD TUMORS

Growths and other space occupying lesions within the spinal canal can be conveniently divided into two groups those which arise within the substance of the spinal cord and invade and destroy tracts and central gray structures (intramedullary) and those which arise outside the spinal cord (extramedullary) from the vertebral bodies and epidural tissues (extradural) the meninges or roots (intradural) The relative frequency of spinal tumors in these different locations in a general hospital is about 5 per cent intramedullary 40 per cent intradural extramedullary and 55 per cent extradural The percentage of extradural lesions is usually higher than in most neurosurgical series (e g Elsberg s figures of 10 67 and 15 per cent respectively) which often do not include many of the lymphomas metastatic carcinomas etc most of which are extradural

The cellular origin of the intramedullary gliomas has been mentioned in the section on intracerebral tumors The proportions of the different cell types differ however Kernohan who has had one of the largest series of pathologic cases found all the gliomas represented in the spinal cord but ependymoma was noted to make up 40 per cent and the remainder were more or less evenly distributed

mors of the optic nerve and angiomas of the orbit must be considered in the differential diagnosis Auscultation of the skull x ray of the skull and carotid arteriography are helpful in differentiating these lesions

MENINGIOMA OF THE OLFACTORY GROOVE This tumor is a growth derived from arachnoidal cap cells along the cribriform plate The diagnosis depends on the finding of ipsilateral or bilateral anosmia ipsilateral or bilateral blindness often with optic atrophy on one side and papilledema without atrophy on the other (Kennedy syndrome) and mental changes The tumors may reach enormous size before coming to the attention of the physician The anosmia if unilateral is rarely if ever reported by the patient The unilateral visual disturbance may consist of a slowly developing unilateral central scotoma Confusion forgetfulness inappropriate jocularity (*Witzelsucht*) are the usual psychic disturbances The patient is indifferent to or jokes about blindness Usually there are x ray changes along the cribriform plate and an extremely high cerebrospinal fluid protein (200 to 400 mg)

GLIOMA OF THE BRAIN STEM Astrocytomas of the *brain stem (formerly called bipolar spongioblastomas)* are slow growing firm white infiltrating growths which insinuate themselves between tracts and nuclei They produce a variable clinical picture depending on their exact location in the medulla pons and midbrain (Chaps 30 and 254 for these syndromes) The characteristic features in the early stages are signs of crossed motor or sensory disturbances which always indicate brain stem disease and as the lesion advances an orderly suc*cession of new signs due to involvement of neigh*boring structures and finally signs of bilateral disease in the brain stem Headache vomiting and papilledema occur late The course is slowly progressive over years unless some part of the tumor becomes more malignant (glioblastoma multiforme) in which instance the illness may terminate fatally within months The main clinical problem is to differentiate between this disease multiple sclerosis and vascular malformations of the pons These so called intramedullary or intrinsic brain stem lesions may usually be distinguished from extramedullary compressive ones by (1) predominance of both tract and nuclear involvement in the former and of cranial nerve involvement in the latter (2) signs of involvement of special intramedullary structures e g internuclear ophthalmoplegia due to affection of medial longitudinal fasciculi or vertical nystagmus which are rarely observed in compressive lesions of the brain stem Pneumoencephalography to visualize the fourth ventricle and *aqueduct and occasionally vertebral* arteriography are helpful in diagnosis The treatment is x ray radiation and if intracranial pressure is increased a Torkildsen ventriculo cisterna magna shunt

GLIOMA OF THE OPTIC NERVES AND CHIASM This tumor is often found in patients with von Recklinghausen s disease and like the glioma of the brain stem is most frequently observed in children and adolescents The initial symptoms are dimness of vision with constricted fields bizarre bilateral field defects of homonymous heteronymous sometimes bitemporal type blindness and optic atrophy with or without papilledema Hypothalamic signs (infantilism adiposity polyuria somnolence and genital atrophy) are common X rays reveal an enlargement of the optic foramen With this finding and the lack of ballooning of the sella or suprasellar calcification pituitary adenoma Hand Schuller Christian disease and craniopharyngioma can be excluded The treatment is surgical excision or x ray depending on the exact location

CHORDOMA This is a soft jellylike gray pink growth composed of cords or masses of large cells with granules of glycogen in their cytoplasm and often multiple nuclei and intercellular mucoid material They are locally invasive but do not metastasize They may arise from any part of the base of the cranium or vertebral column but the commonest sites are the base of the skull (from physaliphora ecchondrosis) or lumbosacral region (giving rise to a cauda equina syndrome) Those in the base of the skull create a remarkable clinical picture in which all or any combination of cranial nerve palsies from II to XII on one or both sides are combined with a retropharyngeal mass and erosion of the clivus of sphenoid bone and the occiput It is one of the four *tumors that may present both as an intracranial* and as an extracranial mass (The other three are the neurofibroma the glomus jugulare tumor and carcinoma of sinuses or pharynx) The treatment is x ray therapy

NASOPHARYNGEAL GROWTHS WHICH ERODE THE BASE OF THE SKULL These are rather common in a general hospital and arise from the mucous membrane of the paranasal sinuses or the nasopharynx near the eustachian tube i e the fossa of Rosenmueller (*transitional cell carcinoma Schmincke tumor*) In addition to symptoms of nasopharyngeal or sinus disease which may not be prominent facial pain and numbness (trigeminal) abducens palsy (sixth cranial nerve) and other cranial nerve palsies may occur Diagnosis depends on inspection and biopsy of a nasopharyngeal mass biopsy of an involved cervical gland and x ray evidence of erosion of the base of the skull The treatment is x ray therapy

Prognosis

The prognosis of intracranial tumor is influenced by the nature of the growth its location and other

the tenth eleventh and twelfth thoracic and the first lumbar vertebrae may result in a curious syndrome of mixed cauda equina and spinal cord symptoms Lesions of the cauda equina alone always difficult to separate from diseases of the plexus and multiple nerves are usually attended in the early stages by pain which is variously combined with an asymmetric atrophic areflexic paralysis radicular sensory loss and later sphincteric disorder This must be distinguished from tumors of the conus medullaris (lower sacral segments of spinal cord) in which there are early disturbance of sphincters of the bladder and bowel back pain hypesthesia and anesthesia over the sacral dermatomes a lax anal sphincter with loss of anal and bulbocavernosus reflexes and sometimes weakness of lower leg muscles A Babinski sign means that the spinal cord is involved above the fifth lumbar segment

Diagnosis

Several problems may arise in the diagnosis of patients with spinal cord tumors First in the early stages spinal tumor must be distinguished from other diseases which cause pain over certain segments of the body i e those affecting the gall bladder kidney stomach and intestinal tract pleura etc Here the localization of the pain to a dermatome its intensification by effort segmental sensory changes and minor alterations of motor reflex, or sensory function in the legs will usually provide the clues to the compressive irritative radicular lesion Examination of the cerebrospinal fluid x ray of the spine and myelography will settle the diagnosis in most instances

If symptoms and signs of disorder of sensory and motor tracts of the spinal cord are present there is still the problem of determining the segmental level of the lesion At first the sensory and motor deficiencies may be most pronounced in those parts of the body furthest removed from the lesion i e in feet or lumbosacral segments Later these sensory and motor levels may rise but at any time they may be far below the lesion Of greatest help here are the locality of the root pains and atrophic paralysis and lastly the upper level of hypalgesia Again myelography is necessary to determine the exact level of the cord compression If localization of the cord lesion in terms of spinal segments has been established there is still the problem of ascertaining the vertebral localization for the two do not correspond (see Chap 255 for a statement of the relationship of spinal segment to vertebrae)

Once vertebral and segmental levels are settled there is still the necessity of determining whether the lesion is neoplastic and is extradural intradural extramedullary or intramedullary This is important from the standpoint of etiologic diagnosis If there is a visible or palpable spinal deformity or x ray evidence of vertebral destruction one may confidently assume an extradural localization Without x ray changes one still suspects extradural lesion if root pain developed early and is bilateral spine ache is prominent and percussion tenderness is marked Motor symptoms below the lesions precede sensory changes and sphincter disturbances are late The distinction between intradural-extramedullary and intramedullary lesions is almost impossible Radicular pain asymmetry of signs of motor and sensory tract involvement and early cerebrospinal fluid blockage (positive Queckenstedt test and high protein) favor the extramedullary localization With extradural lesions one must differentiate between ruptured disk spondylosis (hypertrophic spurring and osteophyte formation in cervical spinal canal) tuberculous caries other pyogenic fungous or syphilitic granulomatous lesions secondary carcinoma or lymphoma With intradural-extramedullary lesions meningioma neurofibroma meningeal carcinomatosis cholesteatoma, teratomatous cyst or meningomyelitic process is most likely Intramedullary lesions are usually gliomas or vascular malformations A negative Queckenstedt test normal or relatively low protein in cerebrospinal fluid and a negative myelogram will serve to rule out intraspinal tumors or granulomatous lesions in most instances

In conclusion it is well always to remind oneself that of the more than 30 diseases of the spinal cord there are available effective means of treating only a few—extramedullary spinal cord tumors syphilis (meningomyelitis and tabes) epidural granulomas (pyogenic tuberculous fungous) subacute combined degeneration and nutritional myelopathy The physician s major responsibility is to determine whether or not his patient has one of the treatable diseases If not exact diagnosis is a matter only of academic interest

Treatment

This varies with the nature of the lesion and the clinical condition of the patient Intradural-extramedullary tumor should be removed Laminectomy decompression marsupialization of cysts and x ray therapy is the treatment of intramedullary gliomas Extradural malignant growths are best managed by the use of opiates for pain x radiation endocrine therapy (for carcinoma of breast and prostate) nitrogen mustard (for certain lymphomas) Sometimes laminectomy and decompression are necessary for diagnosis and prevention of irreversible compressive effects and infarction of the spinal cord With tuberculous caries immobilization of the spine in hyperextension and streptomycin therapy are indicated and laminectomy should be reserved for exceptional cases with complete and irreversible

amongst astrocytomas glioblastomas oligodendrogliomas ganglioneuromas medulloblastomas hemangiomas and hemangioblastomas The hemangioma is the common source of spontaneous hematomyelia and the hemangioblastoma may give rise to a syringomyelia

Pathologic Anatomy and Physiology

Peculiarities of anatomic structure are decisive factors in determining the symptomatology of tumor growths The structure of the spine was described in Chap 255 Traumatic Diseases of the Brain and Spinal Cord The spinal cord hangs as a cylinder within it being moored by the denticulate ligaments and spinal roots There is a small space between the dura and vertebral column which contains fat and a venous plexus and is in communication with extradural tissues through the intervertebral foramens Epidural growth—whether arising as direct extensions from the vertebral bodies by hematogenous dissemination in epidural fat or extension through intervertebral foramens from an extraspinal tumor—may displace and finally compress the spinal cord Masses within the spinal canal may also interfere with its circulation either by blocking the collateral vessels which enter through the intervertebral foramen along the roots or by direct compression of the veins which course longitudinally on the surface of the spinal cord

Intramedullary growths both invade as well as compress and distort fasciculi in the adjacent white matter As the cord enlarges from the tumor growing within it or is compressed from a tumor growing without the free space around the cord is consumed and the cerebrospinal fluid below the lesion becomes isolated or loculated from the rest of the so called circulating cerebrospinal fluid above This can be demonstrated by a positive Queckenstedt test (p 294) Froin s syndrome and interruption of the flow of pantopaque in the subarachnoid space (myelogram)

Symptomatology

Patients with spinal cord tumor are likely to manifest one of two clinical pictures one a radicular spinal syndrome nearly always painful the other a purely sensorimotor spinal tract or rarely a syringomyelic syndrome

Spinal Cord Compression The predominant clinical syndrome relates to spinal cord compression With intraspinal tumors the onset of the compressive symptoms is usually gradual over a period of weeks or months and the course is progressive The initial disturbance is likely to be motor and often the distribution is asymmetric With cervical lesions the order of motor impairment is first the arm then the leg on the same side next the opposite leg and finally the opposite arm With thoracic lesions one leg usually becomes weak and stiff before the other one Subjective sensory symptoms (tingling paresthesias) of spinal tract type take the same pattern Pain and temperature are more likely to be affected than touch vibration and position senses and are contralateral to the maximum motor weakness (Brown Sequard syndrome) Nevertheless the posterior columns are also frequently involved The bladder and bowel usually become paralyzed coincident with motor paralysis of the legs If the compression is relieved there is recovery of these members of the body in the reverse order of their affection the first part affected being the last to recover and sensory symptoms disappearing before motor

Compressive irritative Radicular Syndrome This syndrome of spinal cord compression is often combined with radicular pain i e pain in the distribution of a spinal root It is described as knifelike or as merely a dull ache with superimposed sharp pains which are intensified by cough sneeze or strain and radiation in a distal direction i e away from the spine Segmental sensory changes (paresthesias hyperalgesia impairment of pain and touch) or motor disturbances (spasm cramp twitching atrophy fascicular twitching and loss of tendon reflex) and an ache in the spine are the usual manifestations of a compressive irritative lesion of roots Tenderness of spinous processes over the growth is found in half the patients These segmental changes particularly the sensory ones often precede the signs of spinal cord compression by months or years if the lesion is benign Sphincter disturbances usually appear late

The clinical findings upon examination are spastic weakness of the legs in one leg more than in the other with thoracolumbar lesions and of the arms and legs with cervical lesions a sensory level for pain on the trunk below which pain sense is reduced or lost posterior column signs and a spastic bladder under weak voluntary control

The diagnosis is established by x rays of the spine (erosion of vertebrae widened spinal canal) lumbar puncture and electromyography to demonstrate the fasciculations resulting from involvement of motor roots But the most important diagnostic test of all is Pantopaque myelography for the direct visualization of the compressive lesion Although necessary procedures lumbar puncture and myelography may occasionally exacerbate the symptoms and signs

Special Spinal Syndromes Unusual clinical syndromes may be found in patients with tumors near the foramen magnum *They may produce a quadriparesis* with pains in the back of the head and stiff neck a weakness and atrophy of the hands and dorsal neck muscles and either bizarre sensory changes or no sensory loss whatsoever Lesions of

1 Acute disseminated encephalomyelitis
2 Acute necrotizing hemorrhagic encephalomyelopathy (acute hemorrhagic leukoencephalitis)
3 Multiple sclerosis
4 The neuromyelitis optica syndrome
5 Diffuse cerebral sclerosis

Future investigation may reveal that necrotizing encephalomyelopathy is merely a severe form of disseminated encephalomyelitis and that the neuromyelitis optica syndrome is a variant of the latter disease or of multiple sclerosis It is also possible that in due course certain cases now regarded as acute multiple sclerosis may come to be recognized as constituting another form of disseminated encephalomyelitis However in the absence of concrete evidence the above disorders will be considered individually although it is recognized that at least some of them may be artificially defined

ACUTE DISSEMINATED ENCEPHALOMYELITIS

This term includes cases of postexanthematous postvaccinal and postinfective encephalomyelitis the condition may also be referred to as acute perivascular myelinoclasis In its most typical form it follows vaccination against smallpox and inoculation against rabies In such cases the clinical manifestations follow a relatively stereotyped pattern this is much less true of the encephalomyelitic complications of the exanthems of childhood in which in addition the time relationship to the onset of the exanthem is not so clearly defined Within recent years this group has been broadened to include cases showing encephalitic and/or myelitic manifestations subsequent to nonspecific infective illnesses Adams and Kubik have shown that under such circumstances the pathologic changes are essentially the same as those in the more clearly defined syndromes referred to above

Definition. Acute disseminated encephalomyelitis may therefore be defined as an acute encephalitic and/or myelitic disorder of variable course and severity which is characterized clinically by symptoms indicating damage chiefly to the white matter of the brain and/or spinal cord and pathologically by perivascular cellular infiltration and perivenous demyelination The syndrome may follow smallpox vaccination antirabic inoculation or a nonspecific infective illness (sometimes vaguely referred to as "influenzal") or may develop during the course of an exanthem occasionally it may occur with no clear history of preceding or concurrent infection

Pathology Naked-eye examination of the brain and spinal cord reveals no distinctive changes save for vascular congestion of doubtful significance Microscopically the white matter shows innumerable small zones of demyelination from 0 1 to 1 0 mm in diameter which invariably surround small or medium sized veins Conspicuous subpial demyelination is a prominent feature and is probably related to the profusion of small veins in these situations a similar relationship can also be adduced to explain the areas of subependymal demyelination which are frequently seen around the third and lateral ventricles Silver stains generally demonstrate the integrity of the axis cylinders within the lesions though they may be damaged as shown by their tortuosity and thickening Reacting microglial cells are seen in the demyelinated areas and there is also perivascular infiltration with lymphocytes histiocytes and plasma cells sometimes slight and sometimes massive Meningeal infiltration although invariable is rarely marked. Detailed observation reveals that nearly all the lesions are of the same age and that they are usually scattered throughout the length and breadth of the nervous system indicating simultaneous involvement of the entire neuraxis In other instances however they may be more severe in one part of the nervous system than another thus determining the primarily encephalitic or myelitic nature of the illness It is of course likely that in cases which recover the pathologic changes are less widespread and severe and there is evidence to show that they may be almost, if not entirely reversible

Etiology In this form of demyelinating disease above all, there is much evidence to suggest that one is dealing with an allergic response of the nervous system to an unidentified antigenic agent The main support for this hypothesis lies in the close resemblance of the pathologic findings in such cases to those observed in experimental allergic encephalomyelitis

Clinical Manifestations In view of the pleomorphism of the clinical picture of disseminated encephalomyelitis depending as it does upon the nature of the primary disease which it complicates it will be convenient to subdivide this section with reference to identity of the preceding or concurrent infection

Postvaccinal Encephalomyelitis Encephalomyelitis following antismallpox vaccination is by far the commonest disorder of this type though an identical syndrome may follow inoculation against rabies and a similar illness may rarely occur after smallpox itself A number of epidemics of the post vaccinal type occurred in Holland and England in the 1920s, when it became evident that the disorder affected both sexes equally was commonest in children of school age and was much more frequent after primary vaccination than revaccination. In Holland it affected roughly one person in every 2 300 primary vaccinations and one in every 50 000 revaccinations

In most instances the disease develops between

spinal block Immobilization of the neck and later a collar (Thomas or other) is the treatment of choice in spondylosis Only in a rapidly advancing compressive spinal cord syndrome in a relatively young person should there be a laminectomy and cutting of the denticulate ligaments

TUMORS OF THE PERIPHERAL NERVES

These tumors are discussed in Chap 260

257 DEMYELINATING DISEASES

John N Walton

It is well recognized that there exists a large and important group of diseases of the nervous system all of which are characterized pathologically by a destructive process involving the myelin sheaths of nerve fibers Despite this single common feature there are numerous variations in the clinical manifestations and in the severity and distribution of the pathologic changes which serve in typical cases to distinguish the several disease entities within the group Nevertheless it may at times be impossible to classify an individual case with certainty so ill-defined are the clinical and pathologic margins which separate the constituent disorders

CLASSIFICATION

Any classification of diseases in medicine must depend upon a combination of evidence from three sources one etiologic another clinical and the third pathologic The lack of clear definition in any one of these three fields has led to the difficulties now experienced when attempting to classify the demyelinating diseases Although a familial incidence has been observed occasionally there is no clear evidence to suggest that genetic factors play a fundamental part in their *causation It is also* true that while many theories of etiology—infective metabolic allergic and vascular—have been invoked none conforms entirely to the observed facts *An allergic* process seems very probable in cases of acute disseminated encephalomyelitis and *may well be the basis of the disease state in* other conditions within the group but knowledge is still incomplete so that in most instances the etiology remains obscure Clinically there is no doubt that the natural history of the illness in a chronic relapsing case of multiple sclerosis is entirely different from that observed in say acute disseminated encephalomyelitis following measles On the other hand a distinction on purely clinical grounds between acute multiple sclerosis and subacute encephalomyelitis may be impossible the existence of such transitional and borderline cases precludes a classification based entirely upon clinical criteria

Similar difficulties arise in considering pathologic data In general the basic process is one of destruction of myelin sheaths with relative sparing of nerve cells axis cylinders and supporting structures however the distribution and severity of the lesions vary greatly In one disease the foci may be multiple small and widely disseminated in another they are large and spreading outward from one or a few centers sometimes they are all perivenous but in other cases this is only partially true Whereas in one instance the axis cylinders are virtually intact despite severe myelin destruction in another they may suffer to an almost equal extent From the pathologic as well as the clinical standpoint intermediate or transitional changes may be seen bridging the gap between disease entities which have been customarily though artificially defined The source of these difficulties springs from the probability that myelin destruction is not the primary process but merely a response of the nervous system to a variety of noxae Definition of such etiologic factors if achieved must surely lead to a clearer understanding of the clinical and pathologic changes observed and in turn to a firm classification In the meantime correlation of the available information from all sources would support the following classification as the most practical

a transient illness occurs with headache drowsiness and neck stiffness in others there may be a severe ataxia and occasionally athetotic movements while in yet others the typical picture of transverse myelitis develops Whatever the clinical manifestations the prognosis is good death is uncommon and over 90 per cent of patients make a complete recovery

In postexanthematous cases as in the postvaccinal the cerebrospinal fluid may rarely be normal but usually contains an excess of lymphocytes and protein. Diagnosis is comparatively easy in the presence of the exanthem

Postinfective Encephalomyelitis. This group includes a heterogeneous collection of cases in which an encephalomyelitic illness succeeds a respiratory tract infection or an influenzalike illness it is probably desirable that it should be broadened yet further to embrace cases of similar clinical course showing identical pathologic features in which there is no history of a preceding illness

The clinical manifestations in cases in this group may vary from the typical picture of severe disseminated encephalomyelitis with deepening coma and flaccid paraplegia on the one hand to a mild illness with headache drowsiness fever and perhaps transient limb or bulbar pareses on the other Myelitic syndromes may occur though in a considerable proportion of these cases the disease process also affects the brain stem giving nystagmus impairment of ocular movement dysphagia, facial weakness and variable long tract signs Evidence of nerve root involvement is common in cases where the disorder is primarily spinal and the condition may then resemble the closely related idiopathic polyneuritis (Guillain-Barre syndrome) In many other cases there will be a striking resemblance to the accepted clinical manifestations of acute multiple sclerosis However a follow up study carried out by Miller and Evans on cases of this type has shown that they do not develop further neurologic episodes during the succeeding years

Cerebrospinal fluid changes as in the other forms of acute encephalomyelitis are not diagnostic and in these cases particularly those with no history of preceding infection diagnosis may be very difficult. The development of coma and flaccid quadriplegia following an influenza like illness is distinctive but on other occasions virus encephalitis multiple sclerosis and bulbospinal poliomyelitis may be mimicked. Indeed accurate diagnosis may depend in the last resort upon pathologic evidence and even this *may fail to distinguish the condition* from multiple sclerosis In the present state of knowledge it is difficult to glean accurate information about prognosis A considerable proportion of comatose and quadriplegic patients die those in whom the neurologic signs are relatively mild usually recover but in the intermediate group it is impossible to predict with certainty which patients will be left with residual evidence of neurologic deficit

Treatment In an attempt to prevent the occurrence of postvaccinal encephalomyelitis some authorities consider it unwise to carry out primary *vaccination in a young adult unless he has been* in contact with a case of smallpox, or during an epidemic. This view is not generally accepted. Other prophylactic measures are probably of little avail.

Benefit has been claimed for the administration of immune human serum 10 ml intravenously both in cases appearing after vaccination and in those following or complicating the exanthems failing this an intramuscular injection of immune citrated whole blood may be given Numerous workers also pay tribute to the value of daily or twice daily lumbar punctures Recent work has suggested that cortisone and ACTH have a beneficial effect. Despite the difficulty of carrying out accurately controlled trials in order to assess results it seems sensible to use one or another of these remedies

ACUTE NECROTIZING HEMORRHAGIC ENCEPHALOMYELOPATHY

In a small number of patients dying from a fulminating encephalopathic illness certain distinctive pathologic features may be found On section of the brain, the white matter of one or both hemispheres is seen to be destroyed almost to the point of liquefaction The involved tissue is pink or yellowish gray and flecked with multiple small hemorrhages Sometimes similar changes are localized to the brain stem On histologic examination one finds widespread necrosis of small blood vessels necrosis of brain tissue around the vessels with intense cellular infiltration, multiple small hemorrhages and a violent inflammatory reaction in the meninges The pathologic picture resembles disseminated encephalomyelitis in its perivascular distribution and diffuse sclerosis in its tendency to congregate into large foci in the cerebral hemispheres

The clinical course of the illness resembles acute disseminated encephalomyelitis save for its apoplectiform onset and rapidity of progress leading often to death within 48 hr it is also true that neurologic signs are frequently unilateral or purely bulbar in type reflecting the localized nature of the pathologic process It is probable that certain patients *showing an explosive myelitic illness* are suffering from a necrotizing myelitis of similar type but pathologic evidence in support of this view has been difficult to obtain The cerebrospinal fluid reveals a more intense reaction than in other demye-

the seventh and twelfth days after vaccination though the period may be shorter after revaccination The onset is generally abrupt with headache drowsiness fever and vomiting There may be neck stiffness and other signs of meningeal irritation at this stage while convulsions are occasionally seen Soon afterwards signs of spinal cord involvement usually appear with flaccid paralysis of the limbs which may be hemiplegic in distribution but more commonly involves all four limbs Tendon reflexes disappear and the plantar responses become extensor Sphincter control is generally lost and sensory loss though variable may be extensive and severe Nystagmus ocular palsies pupillary changes and sometimes trismus may give evidence of brain stem involvement while extension of the cerebral affection may lead to stupor and deepening coma Despite these general features of the typical case numerous variations occur less commonly so that one patient may suffer a predominantly encephalitic illness with little evidence of cord damage another may have a hemiplegia while sometimes a purely myelitic syndrome may occur with no headache neck stiffness or clouding of consciousness Less frequently still a syndrome suggesting involvement of nerve roots or even peripheral nerves may develop Usually the site of vaccination is not remarkable although a few patients show a generalized erythematous rash and others generalized vaccinia The cerebrospinal fluid almost invariably shows an increase in protein and lymphocytes but in rare cases it is normal

DIAGNOSIS The association with vaccination or inoculation will usually leave the diagnosis in little doubt and the characteristic combination of encephalitic and myelitic features will readily distinguish the condition from meningitis virus encephalitis tetanus and poliomyelitis Rarely an atypical case may mimic any one of these disorders In the radicular form there may be difficulty in differentiating the condition from idiopathic polyneuritis

PROGNOSIS Between 30 and 50 per cent of cases reported have died within 4 to 5 days of the ictus usually in deep coma with terminal evidence of medullary paralysis Improvement with recovery of consciousness and regression of neurologic signs occurs in the remaining cases and may be surprisingly complete Miller has shown however that a significant proportion of patients show residual neurologic signs intellectual impairment and/or psychoneurotic sequelae many years after the illness

Postexanthematous Encephalomyelitis More cases of encephalomyelitis have been described after measles than after any other exanthem but occasionally rubella and chickenpox have been complicated in this way The exact status of the neurologic complications of scarlatina whooping cough and mumps has yet to be defined Miller Stanton and Gibbons have shown that lymphocytic meningitis is the principal complication of scarlatina and mumps and in the latter condition it is probably due to invasion of the nervous system by the virus However in a proportion of cases of mumps and very rarely in scarlatina a true demyelinating encephalomyelitis may occur The encephalopathy of pertussis which is fatal in over a third of cases and may leave disabling sequelae in many others is entirely different pathologically and may be hypoxic in origin

Encephalomyelitis complicating *measles* generally begins 2 to 4 days after the appearance of the rash but may antedate it and may even occur in patients with a history of contact who do not develop a rash The clinical picture is variable indeed but may resemble that described under postvaccinal encephalomyelitis indicating the presence of widespread lesions throughout the white matter of the neuraxis in various combinations The most common clinical syndrome is one dominated by convulsions and deepening coma most fatal cases fall into this group Less commonly the patient may suddenly develop a hemiplegia as if from a cerebral vascular accident or show evidence of severe cerebellar disease while occasionally there develops the clinical picture of transverse myelitis or that of polyradiculitis Athetoid movements resulting from involvement of the basal ganglions are also seen infrequently In many cases however the disease is much less severe and the patient suffers a transient encephalitic illness with headache confusion and signs of meningeal irritation About a tenth of the patients succumb to the disease or to intercurrent infection however less than half the remainder recover completely and the others remain more or less severely disabled with hemiplegia paraplegia cerebellar ataxia fits or mental impairment It is not entirely certain that all the neurologic complications described are truly encephalomyelitic and in some cases cerebral vascular disease particularly thrombophlebitis may be responsible

In *rubella* a diffuse and fatal encephalomyelitic illness may rarely occur and in other uncommon cases a syndrome suggestive of polyradiculitis has been described but more often a mild and transient encephalitic illness develops The neurologic complications of *chickenpox* are similarly benign and usually occur in the second week after the rash has appeared though they can arise at the onset of the illness It is possible that in some cases the varicella virus which is closely related to that of herpes zoster is directly responsible for the patient's symptoms There is no doubt that in others characteristic perivenous lesions unlike those of virus infection have been observed In most cases

tiple sclerosis or that in other cases they have been responsible for producing a relapse Nonspecific and specific febrile illnesses pregnancy surgical opera tions trauma lumbar puncture and many other factors have been invoked from time to time An increasing volume of statistical evidence suggests that pregnancy and lumbar puncture have no in fluence upon the course of the disease but Mc *Alpine and Compston believe* that there is some times a significant relationship between infective illness or local trauma on the one hand and onset or relapse on the other There also seems to be little doubt that the onset of the disease or a relapse may occasionally appear to be precipitated by emotional stress

Incidence Multiple sclerosis is a common dis ease in Europe being particularly prevalent in Switzerland and Scandinavia *It occurs less fre* quently on the American continent and is rare in Africa and Asia It is commonest in the white races but does occur in the Negro

It affects the two sexes approximately equally and usually begins between the ages of twenty and forty some cases develop in the second decade and an increasing number are being re ported in which the onset was in the forties or fifties

Clinical Manifestations *Chronic Relapsing Type* Given a clear understanding of the pathologic changes outlined it will be evident that the clinical features of the disease may be very variable de pending upon the situation and intensity of the lesions It is clear that if it begins with a single discrete lesion there may be a great variety of presenting symptoms depending upon its site on *the other hand* if multiple *lesions occur simultane* ously in eloquent areas of the nervous system a much more specific clinical picture will result This variation in spatial distribution of the areas of demyelination is responsible for the remarkable clinical pleomorphism of the disease to which any experienced neurologist will attest Symptoms at tributable to a single lesion almost invariably remit to be followed by other manifestations at a later date *the same is largely true of other cases in* which there is clinical evidence of multiple lesions initially but in which the onset is acute In cases of these two types numerous relapses may occur each followed by a remission but each leaving in its wake further evidence of permanent neurologic deficit upon which every succeeding acute mani festation is superimposed As a rule such a patient eventually reveals a clinical state indistinguishable from that observed in another type of case which from the start can be recognized as harboring multiple disseminated lesions all progressing inex orably at much the same rate The relapsing type with multiple acute and subacute episodes is of course commoner in younger patients while the slowly progressive form is most frequent in pa tients whose disease begins in middle age in these latter individuals the major burden of the disease process generally falls upon the spinal cord

Having mentioned these general features it may be said that numerous characteristic symptom com plexes may be recognized as occurring within the structure of the disease process and are best classi fied according to the mode of onset It should be stressed that despite the variability of initial ex pression of the disease most cases after a greater or lesser period of time follow a final common path of increasing spasticity immobility respiratory or urinary infection and death McAlpine believes that in a small proportion of cases the disease may be arrested spontaneously

The more common symptom complexes observed in this disease are outlined below

1 TRANSIENT WEAKNESS OR LOSS OF CONTROL OF THE LIMBS This symptom may involve one limb (monoparesis) or both limbs on the same side (hemiparesis) but more often both lower limbs are involved (paraparesis) The patient has diffi culty in walking or in using the affected limbs and physical examination during the episode reveals evi *dence of corticospinal tract and/or cerebellar* dis ease These early manifestations frequently resolve completely only to be succeeded by others after months or years

2 VISUAL SYMPTOMS Sudden loss of vision in one eye (due to retrobulbar neuritis) or diplopia are common initial symptoms of this disease and invariably remit sometimes as long as 20 years may elapse before other features develop

3 SENSORY SYMPTOMS *The* disease may begin with numbness and paresthesias in a limb or limbs and these symptoms being transient may well be overlooked The so called useless hand syndrome in which the patient complains of clumsiness or uselessness of the hand lasting for some days or weeks must be included in this group being gen erally due to impairment of position sense from a lesion in the posterior column of the cord Less fre *quently there may be symptoms* to suggest loss of temperature sensation in one lower limb and the patient is found to have a partial Brown Sequard syndrome due to a plaque in one lateral column These manifestations too almost invariably remit

4 SLOWLY PROGRESSIVE CLUMSINESS AND WEAK NESS OF LIMBS In certain young patients the dis ease may be slowly progressive without clinical remission and in such individuals there is usually evidence of widespread *lesions most often they* show temporal pallor of the optic disks nystagmus cerebellar ataxia and weakness and spasticity of the limbs In the commoner intermittently progressive type which begins in middle life the corticospinal

linating diseases showing a polymorphonuclear pleocytosis and a considerable increase in protein

The etiology and essential nature of this condition remain obscure but the resemblance to the other demyelinating diseases should be noted a resemblance which is strengthened by the fact that certain cases showing the typically fulminating clinical picture have recovered some completely others with neurologic sequelae of variable severity The points of similarity are probably sufficient to suggest that ACTH or cortisone treatment should be tried in cases of this type

MULTIPLE SCLEROSIS

Multiple sclerosis commonly termed *disseminated* or *insular sclerosis* or *sclérose en plaque* is one of the commonest chronic neurologic diseases While pleomorphic in its clinical presentation numerous symptom complexes have come to be recognized as characteristic of the disease so that usually diagnosis is a matter of little difficulty On the other hand many acute cases show notable clinical and pathologic affinities with disseminated encephalomyelitis and with the syndrome of neuromyelitis optica Despite this lack of definition of the borderline case much less is known concerning the etiology of multiple sclerosis than is the case with the acute demyelinating disorders previously described

Definition Multiple sclerosis may be defined as a disease of obscure etiology characterized clinically by symptoms indicating the presence of multiple lesions in the white matter of the brain and spinal cord In most cases there are relapses interspersed with long periods of remission but in others it presents as an intermittently progressive disease with paraplegia and added cerebellar and brain stem signs the latter state is also the eventual outcome of the relapsing cases Pathologically there are multiple plaques of demyelination and gliosis of varying age throughout the central nervous system

Pathology Since the original description of the pathologic changes in this disease by Cruveilhier in 1835 and Carswell in 1838 there have been numerous valuable presentations notably those of Dawson Hassin Zimmermann and Netsky and Adams and Kubik Macroscopically the brain and spinal cord generally show no evidence of disease but the surface of the spinal cord may feel uneven On section numerous scattered lesions are seen which are slightly depressed and by virtue of their pinkish gray appearance (due to loss of myelin) stand out in contrast with the surrounding white matter The lesions may vary in diameter from 1 mm to several centimeters they affect principally the white matter and the roots of cranial nerves but also encroach frequently on cerebral gray matter much less often spinal roots and spinal gray matter are involved The lesions appear to have a predilection for the optic nerves and chiasm and the paraventricular areas of the brain while in the spinal cord the subpial region is often predominantly affected

The histologic appearances depend upon the age of the lesion Relatively recent lesions show a predominantly perivenous distribution of the demyelination with sparing of axis cylinders degeneration of oligodendroglia neuroglial reaction and perivascular infiltration with mononuclear cells Later large numbers of microglial phagocytes infiltrate the lesion as astrocytes in the locality increase in number and size A long standing lesion on the other hand will show thickly matted relatively acellular fibroglial tissue with only occasional perivascular macrophages in such a lesion intact axis cylinders may still be discovered but many are destroyed and this in turn leads to descending and ascending degeneration of long fiber tracts All gradations of pathologic change between these two extremes may be found in lesions of variegated size and shape Save in the most acute cases the distribution is not so strikingly perivenous as it is in disseminated encephalomyelitis

Etiology Little concrete information is available concerning the etiology of this disease save for its occasional familial incidence Pratt Compston and McAlpine have shown conclusively that it occurs in more than one member of a family more often than could be accounted for by chance This should not be taken to indicate that the disease is transmitted as a genetic trait but rather it suggests that there may be an inherited predisposition making an individual more susceptible to the unknown agent or agents responsible for the demyelinating process

None of the numerous theories advanced to explain this disease has been validated Infection by a spirochete or filtrable virus has been adduced and it has been suggested that thrombosis of venules is responsible while other workers on the basis of an analogy with sway back disease of sheep have suggested copper deficiency as an etiologic factor Yet other investigators claim to have demonstrated abnormal enzymes or poisoning with lead The very multiplicity of theories pays tribute to the lack of concrete evidence and recent experimental work has added little that is conclusive Lumsden believes that degeneration of the oligodendrocytes may be the primary factor in producing demyelination but this too is open to confirmation There is far less evidence to support the role of allergy as a causative agent in multiple sclerosis than in the case of disseminated encephalomyelitis

Precipitating Factors It has been suggested frequently that various infective and traumatic agencies have provoked the initial symptoms of mul

trophic lateral sclerosis and subacute combined degeneration may be closely mimicked but the presence of muscle wasting and fasciculations will identify the former and the latter can be confirmed by the absence of acid from the gastric juice by the anemia in most cases and by the presence of megaloblasts in the bone marrow

Cases with a progressive spastic paraplegia may be suspected of having an intrathecal neoplasm or cervical spondylosis Pain and extensive sensory loss are common in the former and rare in multiple sclerosis in which muscle wasting due to anterior horn or spinal root involvement (as sometimes seen in spondylosis) is almost unknown Basilar impression of the skull or platybasia must also be considered but in such patients there is characteristic shortening of the neck and radiographs of the base of the skull are diagnostic Careful clinical appraisal will usually lead to accurate diagnosis but in occasional cases the problem can be resolved only by recourse to cerebrospinal fluid examination radiography of the spinal canal and myelography

PROGNOSIS The duration of the disease is variable Some patients die within a few months others live 30 years or longer In general patients whose disease runs a relapsing course live longer but accurate prediction of the progress in an individual case is impossible The average total duration from the time of the first symptom is 15 to 20 years The final state of the bedridden incontinent patient racked by painful flexor spasms of the lower limbs and shaken by febrile episodes of intercurrent infection is one of the most distressing in medicine it is fortunate that many individuals retain their euphoria to the end

TREATMENT Despite the large number of remedies which have been tried no drug therapy appears to have any influence on the course of the disease ACTH and cortisone appear to be of no value and claims for the efficacy of arsenicals vasodilators and a low fat diet have not been substantiated

The most that can be done is to encourage and reassure the patient through moderate exercise and supportive measures and to keep him mobile and actively employed for as long as possible During an acute episode of the type which invariably remits it is surely preferable to assure the patient that he will recover and to preserve silence on the subject of relapse in view of the long periods of remission which may occur No patient with this disease should be told its nature until the fact becomes self evident and even when all hope of remission seems past the patient should be advised that improvement is still possible

In the late bedridden stage little can be done beyond meticulous care of the skin bladder and bowels but vigorous administration of analgesics or sometimes even rhizotomy or cordotomy may be required to ease the pain of flexor spasms in the legs

THE NEUROMYELITIS OPTICA SYNDROME

This disorder also referred to as *diffuse* or *disseminated myelitis with optic neuritis ophthalmoneuromyelitis* and *Devic s disease* is probably not a distinct nosologic entity as it resembles on the one hand multiple sclerosis and on the other disseminated encephalomyelitis and necrotizing encephalomyelopathy Clinical surveys of patients presenting with this syndrome tend to favor its identification as a form of multiple sclerosis but pathologic studies of fatal cases particularly those in which cavitation of white matter is found have often revealed a more acute and uniformly severe destructive process than is usually seen in the latter disease In the absence of any authoritative evidence to indicate in which group the condition rightly belongs it will be considered as a clinical syndrome with full recognition of the fact that its exact nature is not yet established

Definition Neuromyelitis optica is a syndrome produced by a subacute demyelinating process involving the optic nerves and spinal cord this process may be self limiting and reversible or may be progressive

Pathology To the naked eye the optic nerves and spinal cord are often soft swollen and congested Microscopy reveals extensive demyelination in the optic nerves and chiasm and a similar process is seen in the spinal cord sometimes localized to a few cervical segments and sometimes more extensive Axis cylinders are relatively intact though swollen and irregular there is microglial reaction in and around the demyelinated areas and perivascular infiltration with mononuclear cells is seen

Clinical Manifestations The syndrome affects the sexes equally and can probably occur at any age even during the first decade of life In the so called typical case there is often pain in the eyes followed by impairment of vision first in one eye but affecting the other within a few hours or days Visual loss is variable in extent characteristically there are bilateral central scotomas but total blindness may occur and one eye may be more severely affected Papilledema is sometimes seen but the optic disks often look normal Soon afterwards the characteristic picture of a transverse myelitis appears with flaccid paralysis loss of sphincter control absence of tendon reflexes and extensor plantar responses and variable sensory loss in the extremities depending on the level of the lesion The sensorium is not affected Occasionally the spinal cord syndrome precedes the visual disturbance It is possible that certain cases of bi

tracts are predominantly affected though there is usually some loss of position and vibration sense in the lower limbs indicating posterior column in addition to lateral column disease

5 SYMPTOMS OF PRIMARY BRAIN STEM INVOLVEMENT Some patients may present evidence of predominantly cerebellar disease and it is often these individuals who show Charcot s triad of nystagmus scanning or syllabic speech and intention tremor this form is somewhat uncommon Another group of cases may suffer a transient episode of severe vertigo and vomiting because of a lesion affecting the vestibular connections and may then go for years before other symptoms develop The same is generally true of patients showing evidence of a pontine lesion some of whom may have transient facial anesthesia followed months later by tic douloureux and later still by evidence of spinal cord disease on other occasions tic douloureux may develop in a patient showing overt manifestations of the disease

Acute Multiple Sclerosis Occasionally cases of multiple sclerosis run an acute or subacute course leading to death in weeks or months or else a series of symptoms may develop rapidly and then remit partially or completely to be followed by characteristic relapses In some such individuals the onset is marked by headache vomiting and delirium and by a succession of symptoms indicating severe involvement of the brain stem as described above or of the brain optic nerves or spinal cord In the so called cerebral cases there may be mental changes convulsions aphasia hemianopia and variable long tract signs whereas the spinal type may show the picture of a transverse myelitis These forms of the disease are uncommon and may be very difficult to distinguish from disseminated encephalomyelitis and neuromyelitis optica

Motor symptoms are generally due to corticospinal tract or cerebellar involvement or to a combination of the two Corticospinal tract disease gives a spastic gait and muscular weakness of upper motor neurone type with exaggeration of tendon reflexes in the affected limbs and extensor plantar responses Cerebellar disease results in intention tremor and clumsiness in the performance of fine coordinated movements and the gait is often characteristically broad based and ataxic Involvement of central cerebellar connections gives nystagmus on lateral gaze with the quick phase in a lateral direction

Sensory symptoms such as paresthesias and uselessness of the limbs are due to posterior column involvement and in such cases loss of position sense of two point and tactile discrimination and of vibration sense will be observed and if the changes are extensive Romberg s sign will be positive

Visual loss is due to retrobulbar neuritis which may produce pain in the eye and sometimes disk swelling vision gradually returns after weeks or months and central scotomas may persist while the temporal half of the optic disk becomes pale Such pallor is frequently seen in the absence of any history to suggest an acute neuritic episode Diplopia is occasionally due to selective involvement of one of the oculomotor nerves but more often is of central origin occurring without objective ocular palsy Paralysis of conjugate ocular deviation particularly internuclear ophthalmoplegia is frequent Horner s syndrome occurs rarely but the pupils are usually unaffected

Hysterical features are not uncommon in patients with multiple sclerosis and may make diagnosis difficult while some individuals eventually show evidence of dementia Although euphoria or pathologic cheerfulness is generallly regarded as characteristic many patients are depressed

The sphincters are often involved precipitancy of micturition is characteristic in the early stages but later there may be both fecal and urinary retention Rarely fecal incontinence occurs alone

CEREBROSPINAL FLUID A small proportion of cases particularly the more acute ones show a slight mononuclear pleocytosis The protein content may be normal but there often is slight excess of globulin The latter is most characteristic occurring in perhaps 50 per cent of cases and is indicated by an abnormal colloidal gold curve usually paretic first zone in type but occasionally mid zone in type in the presence of a negative Wassermann reaction

DIAGNOSIS In a characteristic case the evidence of wide dissemination of lesions throughout the neuraxis leaves the diagnosis in little doubt Indeed it is an axiom that the disease should not be diagnosed when all the patient s symptoms and signs can be explained by a single lesion Occasionally this rule must be ignored in the presence of one of the characteristic symptom complexes already described but it is a valuable guide For reasons already given distinction from disseminated encephalomyelitis and neuromyelitis optica is particularly difficult in the acute case but bilateral visual loss as well as stupor and coma are rare in multiple sclerosis while disseminated encephalomyelitis is a self limiting monophasic disease Other acute manifestations may mimic labyrinthitis meningovascular syphilis and encephalitis the first may be recognized only by the course of the disease and then not with certainty but cerebrospinal fluid examination will generally identify the other conditions

Confusion may occasionally arise with the familial ataxias which are generally distinguished by their familial incidence the occurrence of skeletal abnormalities and other associated genetic traits and by their stereotyped clinical pattern Amyo

The disorder often begins with slowly progressive visual failure usually affecting both eyes simultaneously but occasionally beginning unilaterally These features are succeeded by focal or general fits dysphasia mental deterioration and variable weakness of the limbs leading eventually to total blindness dementia and spastic quadriplegia On occasion the onset may be sudden with headache stupor and convulsions in which case visual failure develops later Nystagmus is common but other ocular signs are rare if the pathologic change spreads to the temporal lobe deafness may result

The cerebrospinal fluid is generally normal but may show a slight increase in protein and mononuclear cells

Diagnosis. In a child presenting with visual loss fits progressive dementia and spasticity the diagnosis is often self evident but even in such cases there may be difficulty in differentiation from cerebral lipoidosis *or subacute inclusion encephalitis* In lipoidosis e g Tay Sachs disease there will generally be a history of affection of other members of the family but diagnosis from subacute encephalitis may be impossible clinically differentiation is only of academic interest since all these disorders *are progressive and ultimately fatal* The electroencephalogram which shows paroxysmal and bilaterally synchronous slow wave complexes in subacute encephalitis and almost continuous irregular spike and wave activity in lipoidosis may be of great value in making the distinction since cases *of Schilder s disease show only diffuse slow rhythms* Cases arising in later life may be confused with intracranial tumor necrotizing hemorrhagic encephalopathy and presenile or atherosclerotic dementia few cases in this age group save those showing the classical clinical picture are diagnosed during life

Prognosis The disease is steadily progressive usually leading to death within 3 years but uncommonly patients may survive though progressively disabled for longer periods

Treatment No treatment is known to influence the course of the disease though vigorous anticonvulsant therapy may be required for the control of seizures

258 NUTRITIONAL DISORDERS OF THE NERVOUS SYSTEM

Maurice Victor and Raymond D Adams

The modern concept of nutritional disease is of relatively recent development Although the clin

lateral optic neuritis without signs of cord damage may be abortive examples of this syndrome and the same may well be true of a proportion of cases of transverse myelitis

Cerebrospinal fluid changes are not distinctive the fluid may occasionally be normal but more often shows a moderate increase in protein and mononuclear cells

Diagnosis The relationship of this syndrome to disseminated encephalomyelitis and multiple sclerosis has already been mentioned the main reasons for considering it separately are that visual loss is rare in the former and not often bilateral in the latter In cases with optic disk swelling intracranial tumor may be considered in differential diagnosis but this problem will rarely present serious difficulty similarly distinction from optic neuritis of diverse etiology will usually be straightforward since in the latter condition it is general for only one eye to be affected In cases without spinal cord involvement temporal arteritis may come to mind as a possible cause of visual loss but it affects a different age group and the appearance of the temporal arteries is characteristic In other cases the distinction from syphilitic meningomyelitis or cord tumor will generally be made with ease by spinal fluid examination

Prognosis About half the cases die usually from intercurrent infection but the others may recover to a remarkable extent some apparently completely A significant number are left with permanent severe visual loss and paraplegia

Treatment There is no specific therapy for this condition treatment must be directed to palliation of pain and other symptoms and as in any case of paraplegia meticulous nursing care is required

DIFFUSE CEREBRAL SCLEROSIS

In 1912 Schilder first called attention to a disease in which progressive massive demyelination of the white matter of the cerebral hemispheres occurred and the condition was later referred to as *Schilder s disease* or *encephalitis periaxialis diffusa* Since that time many other cases have been described some resembling Schilder s original description others differing in certain specific details An attempt has been made by Krabbe Pelizaeus Merzbacher and others to define certain clinical subgroups on the basis of variations in age of onset familial incidence and clinical course Three broad pathologic types have been distinguished one corresponding to Schilder s original description and another showing changes which cannot be distinguished from those of cerebral multiple sclerosis The third type which has been reviewed in detail by Brain and Greenfield under the name *late infantile metachromatic leukoencephalopathy* is probably a separate disease entity and it may be that the cases of Krabbe and those of Pelizaeus and Merzbacher were in reality examples of this or still a fourth condition

Definition The *diffuse cerebral scleroses* are a group of conditions of unknown etiology some *occurring sporadically* others *running in families* which are characterized clinically by progressive visual failure mental deterioration and spastic paralysis and pathologically by massive demyelination of the white matter of the cerebral hemispheres

Pathology On inspection the brain often appears somewhat shrunken and feels firmer than usual but there are no other distinctive external appearances On section the white matter is seen to be largely replaced by a brownish gray rubbery translucent material which may occasionally show small cavities Usually the process spares the subcortical arcuate fibers thus giving a particularly distinctive appearance The changes are generally most advanced in the occipital lobes and involve the parietal and frontal areas to a variable extent but occasionally they may begin frontally the two hemispheres are often not affected symmetrically Balo has described certain cases in which demyelination occurs in concentric rings surrounding normal areas of white matter Adams and Kubik believe this appearance to be an occasional feature of multiple sclerosis but not of diffuse sclerosis

Histologic examination usually reveals that all myelin has disappeared from the affected areas and that axis cylinders have been involved to an almost equal extent In the older parts of the lesion there is proliferation of fibrous astrocytes but in the more recent areas swollen astrocytes are seen and around the margins of the lesion macrophages are plentiful The oligodendrocytes are almost completely destroyed Perivascular infiltration is minimal but in the vicinity of the more recent lesions the perivascular spaces may contain numerous fat filled macrophages

In the metachromatic form of diffuse sclerosis (Brain and Greenfield) the macroscopic appearances are similar though more symmetric but there is severe degeneration of the interfascicular oligodendroglia and large granular bodies staining metachromatically with thionine are frequent. This condition may well be a primary disorder of myelin development unlike the other demyelinating diseases

Clinical Manifestations In about half the cases the condition begins in the first decade Schilder s original description was of a disease occurring in early childhood but it is now recognized that this pathologic process may occur at any age More males than females suffer in childhood but in later years the sexes are equally affected

as well as *riboflavin* is probably essential for maintaining the integrity of peripheral nerves in some species

EXPERIMENTAL VITAMIN DEFICIENCY IN HUMAN BEINGS

The same method that has been successfully employed in assessing the role of *thiamine deficiency* in animals viz the use of a basal diet with the addition of all the crystalline vitamins except thiamine has been used in human beings Mental symptoms such as irritability depression defective memory and failure of concentration and peripheral symptoms such as parathesias and tenderness of the calves have been readily produced by this procedure The production of neurologic signs specifically those of polyneuropathy has been accomplished on only a few occasions after prolonged periods of deficiency

A different method has been employed in assessing the role of thiamine and other vitamins in the Wernicke Korsakoff syndrome The patients presenting neurologic signs were carefully evaluated over a period of several days while continuing to receive a diet completely lacking or deficient in the B vitamins Various vitamins were then added and the effect on the neurologic signs was noted It has been found that the addition of thiamine alone proved to have a dramatic effect in reversing the ophthalmoplegia as well as the drowsiness and apathy so characteristic of the acute stages of the disease the ataxia improved more slowly and frequently the nystagmus persisted indefinitely in less severe form The amnestic symptoms disappeared very slowly and incompletely and at times not at all

That *pyridoxine* is important in human nutrition was first suggested in 1951 when a large number of infants who were receiving a commercial milk product deficient in pyridoxine developed convulsive seizures Also it was discovered that the neuropathy which occurred in tuberculous patients receiving isonicotinic acid hydrazide (INH) was due to an interference or metabolic antagonism of pyridoxine Polyneuropathy as well as the characteristic skin changes of pellagra have been produced in human volunteers by the administration of a pyridoxine antagonist desoxypyridoxine Similarly abnormalities of the peripheral nervous system have been produced by using an antagonist of *pantothenic acid*

NUTRITIONAL DISEASES OF THE HUMAN NERVOUS SYSTEM

Except for subacute combined degeneration of the cord (vitamin B_{12} deficiency) and certain aspects of Wernicke s disease (vitamin B_1 deficiency) it is not possible to relate clinical syndromes to single vitamin deficiencies It would appear from experimental observations that polyneuropathy may result from one of several vitamin deficiencies Other syndromes such as beriberi which have been repeatedly ascribed to a deficiency of thiamine may be due to a deficiency of several factors This would be suspected where the diet consists mainly of milled rice The etiology of pellagra is even more complex as indicated in Chap 57 For these reasons a clinical classification is suggested comprising the following syndromes

1 Wernicke s disease and Korsakoff s psychosis
2 Nutritional polyneuropathy (neuritic beriberi)
3 Nutritional amblyopia (retrobulbar neuropathy)
4 Pellagra
5 Strachan s syndrome
6 Subacute combined degeneration of the cord

With the exception of subacute combined degeneration of the cord these syndromes are rarely seen in pure form instead there is considerable overlapping from one to another In patients with nutritional disease it is usual for more than one part of the nervous system to be involved this is a point of considerable diagnostic importance for involvement of both the central and peripheral nervous systems is found in only a few clinical circumstances Also the examination of these patients frequently discloses signs of malnutrition aside from those associated with the major neurologic syndrome These include general wasting various mucocutaneous lesions circulatory abnormalities and signs of scurvy

In this country the nutritional disorders of the nervous system are most often observed in the alcoholic population of the large urban centers Alcohol plays only a secondary role however mainly by displacing food in the diet It is also possible that excessive ingestion of alcohol impairs the absorption of nutrients and increases the need for thiamine by adding nonvitamin calories to the diet

Wernicke s Disease

In 1881 Carl Wernicke described an illness of sudden onset characterized by mental disturbance paralysis of eye movements and ataxic gait Swelling of the optic disks with retinal hemorrhages was also said to be present and in all three of his patients there was a progressive depression of the state of consciousness and death A fatal outcome was at one time regarded as a universal feature of this disease Wernicke described focal vascular lesions primarily affecting the gray matter around the third and fourth ventricles and aqueduct of Sylvius He regarded the disease as inflammatory

ical features of scurvy rickets pellagra and beri beri had been known for many years the idea that these illnesses resulted from a lack of essential foodstuffs was entertained for the first time only about the end of the last century Before then it was customary to ascribe disease to the deleterious effects of certain substances in the body i e toxins The suggestion that minute amounts of substances normally present in food could seriously influence the metabolic processes of the body was first clearly enunciated by Funk in 1911 He named these essential substances vitamines His work marked the beginning of the science of nutrition Since that time many vitamins have been isolated and synthesized and their relation to specific syndromes of disease has been demonstrated Also there have been advances in the over all aspects of nutrition—in the preparation storage canning and processing of food and more recently in its distribution to undernourished peoples These steps represent a great stride forward in man s economic and social development

As indicated in Chap 55 deficiency disease in man is not simply a matter of vitamin insufficiency Starvation a completely avitaminotic state is not attended by scurvy beriberi or pellagra Thiamine deficiencies are more likely to develop with diets *high in carbohydrate It should* appear then that a certain amount of food is necessary for the development of these diseases Such factors as exercise growth pregnancy and illness in which there is an increased need for vitamins are influential in the production of an avitaminotic state Also lesions of the intestine and liver may interfere with absorption and synthesis and there is some evidence that the deficiency of one vitamin may be enhanced by the excess of another

Other factors appear to determine the peculiar selectivity of vitamin insufficiency For example during the Second World War Europeans and Canadians developed the so called "electric foot" syndrome whereas the natives of Hong Kong on the same diet almost all escaped this condition Moreover once electric foot had been contracted and recovered from a reexposure to dietary conditions which originally elicited the complaint no longer caused the symptoms to appear The significance of these observations is not clear Nor can it be adequately explained at present why similar deficiencies should cause such diverse syndromes as Wernicke s disease in one group of individuals and the syndromes of amblyopia and polyneuropathy in another

Finally it must be pointed out that there are foodstuffs other than vitamins which are of vital importance Certain amino acids are essential to normal nutrition as for example tryptophan in pellagra (see Chap 57) others probably are of importance although their exact place has not yet been determined

Of the known vitamins only the B group are of importance in diseases of the nervous system With the identification of the various members of this group a large number of experiments were undertaken to elucidate their specific role in the nutrition of the nervous system Most of this work has been done in animals but a considerable body of data has also accrued from experiments on man Conclusions drawn from the experimental work have been indiscriminately applied to human disease resulting in considerable confusion For the sake of clarity therefore the nutritional diseases of the nervous system will be considered from three points of view (1) the animal experimental diseases (2) the human experimental diseases and (3) the naturally occurring diseases in human beings

EXPERIMENTAL VITAMIN DEFICIENCY IN ANIMALS

Although much of the experimental work is open to serious criticism there is a body of experimental data in animals which clearly indicates that the B vitamins are essential in maintaining the integrity of the nervous system *Thiamine deficiency* in the *rat dog pigeon and chick may cause a degeneration* of peripheral nerves and where the dorsal roots or their ganglions are involved of the posterior columns of the spinal cord Lesions of the central nervous system in the region of the vestibular nuclei have been produced in the rat and in the pigeon In fox mink and cat similar lesions of the central nervous system have resulted from the use of a fish diet containing a thiamine destroying enzyme thiaminase These lesions as well as those produced in monkeys by a thiamine deficient diet are similar in their topography and histologic character to those of Wernicke s disease

Pyridoxine deficiency has been found to be regularly attended by convulsions in a large number of species Swine and dogs in addition suffer an ataxia of gait and weakness of the limbs In these animals degenerative changes have been observed in the peripheral nerves dorsal root ganglions the posterior roots and the posterior columns of the spinal cord These findings would explain the weakness and ataxia but in the brains no abnormalities have been found In pyridoxine deficient monkeys abnormalities have been observed in the large nerve cells of the cerebral cortex, consisting of swelling eccentricity of the nuclei and loss of the Nissl particles This cell change bears a strong resemblance to that seen in human pellagra

A deficiency of *pantothenic acid* like that of pyridoxine causes a degenerative change in the peripheral sensory neurones of swine This vitamin

ever indications of disordered cardiovascular function in these patients such as tachycardia exertional dyspnea postural hypotension and minor electrocardiographic abnormalities Occasionally the patient may die suddenly the mode of death suggesting cardiovascular collapse It has been shown that Wernicke s disease is characterized by a state of high cardiac output out of proportion to the oxygen consumption The authors own observations suggest that this is because of an abnormal state of vasodilatation which in turn may be related specifically to thiamine deficiency

Pathologic Changes Views on the pathology of this disease have altered considerably since Wernicke s time It is now known that the disease process is limited neither to gray matter nor to the upper brain stem Hemorrhagic lesions as the original name suggested are not present in all instances and when they are do not necessarily represent the most significant or prominent change Post mortem examination reveals symmetrically located lesions in the paraventricular regions of the thalamus and hypothalamus the mammillary bodies the periaqueductal region of the midbrain and the floor of the fourth ventricle particularly in the region of the dorsal motor nucleus of the vagus The lesions are invariably found in the mammillary bodies and less consistently in the other areas Microscopically the principal change consists of varying degrees of necrosis of parenchymal structures There are a vacuolization of the tissue and a looseness of structure some nerve cells are lost but many are left either in a damaged or normal state Many nerve cells and fibers are destroyed others remain intact and are seen against a background of reactive glial elements both astrocytes and microgliacytes The blood vessels are prominent owing to adventitial and endothelial proliferation Hemorrhages are discrete and usually give the appearance of being of recent origin These microscopic changes are most intense in the center of the lesion shading off towards the periphery where there are some looseness of structure and proliferation of microglial cells and where some nerve cells appear shrunken and eosinophilic All the oculomotor nuclei either are spared entirely or are involved only to a mild degree and the same is true of the medial longitudinal fasciculi which connect them The lack of significant structural changes in these nuclei is consistent with the rapid clinical improvement in oculomotor function Several of the authors cases have also shown cerebellar lesions consisting mainly of a loss of Purkinje cells with the vermis more affected than other parts and the superior vermis more affected than the inferior The cerebellar lesions require further study

Etiology Wernicke s syndrome is no longer regarded as inflammatory in nature or as the result of the neurotoxic effects of alcohol Nutritional deficiency is now established as the causal factor Outbreaks have been encountered in prisoner of war camps and occasional cases have been reported in wasting diseases of varied origin where alcohol played no part The specific nutritional factor in most if not all the symptomatology of Wernicke s disease is thiamine The experimental evidence for this statement both in animals and in man has been mentioned This idea has received confirmation through numerous clinical observations The marked sensitivity of the ophthalmoplegia to the administration of thiamine accounts for the rapid disappearance of this sign following the ingestion of one or two meals The quality of prompt reversibility suggests that these symptoms are due to a biochemical abnormality and not to structural change On the other hand the memory loss responds slowly or not at all suggesting that this symptom is the result of structural changes presumably in the mammillary bodies and adjacent areas in the walls of the third ventricle

Korsakoff's Psychosis

Korsakoff s psychosis is generally defined as a state of memory defect with confabulation These features alone however fail to characterize this disease adequately It was apparent from Korsakoff s writings that his patients displayed a much wider range of symptoms including those of delirium and what he termed irritable weakness" (anxiety fear and depression) Furthermore if one subjects these patients to formal psychologic testing they are found defective in concentration verbal and visual abstraction visual motor coordination and learning ability Although such a pattern is probably not specific for Korsakoff s psychosis it is worth emphasizing that there are in this disease a number of abnormalities in cognitive function apart from those of memory defect Nevertheless as has been repeatedly stressed memory is disturbed out of proportion to other cognitive functions Thus a patient may be capable of performing adequately the problems posed by a standard intelligence test and yet within a few minutes of completing the test be unable to recall either the examiner or having taken the test Although it is recent memory that suffers most this is a relative matter the memory of events preceding the illness is always defective and even remote memory may be defective in severe cases

Of the various abnormalities of memory function two seem to be of particular importance (1) a persistent inability to learn newly presented material i e to make new memories and (2) an inability to recollect past events in their correct temporal sequence The inability to learn newly presented material is quite as distinctive of Korsakoff s psy

in nature and suggested the name *acute superior hemorrhagic polioencephalitis*

Since Wernicke s time views regarding this disease have undergone considerable modification clinically pathologically and etiologically

Symptoms and Signs The crux of the clinical picture is the ocular disturbance the diagnosis of Wernicke s disease at least during life cannot be made without it The usual ocular motor signs consist of (1) nystagmus both horizontal and vertical (2) paralysis of the external recti and (3) paralysis of conjugate gaze These signs show a considerable diversity The paralysis of conjugate movement varies from merely a nystagmus on extreme gaze in one direction to a complete loss of ocular movement in that direction Also vertical movements may be affected though abnormalities of the former are commoner Paralysis of downward gaze is an unusual manifestation of Wernicke s or in fact of any neuroophthalmic disease Next to nystagmus one most frequently encounters a lateral rectus muscle weakness or paralysis The sixth nerve palsy is always bilateral though not always symmetric and is accompanied by diplopia and internal strabismus With lateral rectus paralysis there may be an initial absence of nystagmus in the abducting eye the nystagmus becoming evident as the weakness improves In advanced stages of the disease there may be a complete loss of ocular movement and the pupils which ordinarily are spared may become miotic and non reacting Other ocular disturbances such as ptosis retrobulbar neuropathy retinal hemorrhages involvement of the near far focusing mechanism and internuclear ophthalmoplegia are decidedly rare although they do occur on occasion The authors have never observed papilledema in this disease

The ataxia is mainly one of stance and gait In its severest form the patient is literally unable to stand or walk without support The mildest degree of ataxia may be brought out only by special tests such as heel to toe walking In contrast to the gross disorder of locomotion is the relative infrequency of a clear cut intention tremor When present it is more likely to be encountered on heel to shin than on finger to nose testing Scanning speech is present only in isolated instances The ataxia of gait is most likely cerebellar in origin *but it is often* mistakenly attributed to a polyneuropathy

Affection of the peripheral nerves is common in Wernicke s disease occurring in over half the patients in the majority of these patients however the signs of neuropathy are so slight that they could not account for the disordered gait Nevertheless in a small proportion the neuropathy is so severe that stance and gait cannot be tested

The third consistent clinical feature of Wernicke s disease is the mental disturbance Several distinct groups of mental symptoms can be recognized as follows

1 The characteristic mental symptoms of delirium tremens or its variants i e hallucinations and other disorders of sense perception confusion agitation and autonomic overactivity The symptoms *are evanescent in nature and may clear with* out any treatment

2 A mental disorder the outstanding feature of which is apathy listlessness and severe confusion Unconsciousness as part of the initial episode is distinctly rare and also drowsiness is not common Instead the patient s mental state is better described as one of lack of interest or indifference His spontaneous speech is minimal and he is inattentive and cannot concentrate on the simplest task Many questions directed to him go unanswered or he may suspend conversation in the middle of a sentence to turn over and sleep He is readily roused from this state however What questions the patient answers betray disorientation in time and place misidentification of those around him and an inability to grasp the meaning of his illness or immediate situation Many of his remarks are irrational and show no consistency from one moment to another Under these circumstances a proper evaluation of the mental status is seldom possible When the patient s interest and attention can be maintained for a long enough period to ensure adequate testing one usually finds an impairment of retentive memory and of other cognitive functions If these patients are given thiamine or simply an adequate diet they lose most of these symptoms in a matter of days They become more alert attentive and responsive and in general more able to take part in mental testing At this time it becomes evident that the most prominent abnormality is one of retentive memory or what is ordinarily regarded as Korsakoff's psychosis

3 The characteristic disorder of retentive memory and of other cognitive functions that is recognized as Korsakoff's psychosis

The symptoms may have an acute onset and all of them may appear at the same time More frequently however the ophthalmoplegia and ataxia precede the mental signs by a few days or a week Unlike the patients described by Wernicke all of whom *died a lethal termination is not invariable* Only 16 per cent of the authors patients died and they had an illness complicated by other serious diseases such as cirrhosis of the liver or tuberculosis These patients may also show other stigmas of malnutrition the most frequent of which is polyneuropathy Occasionally amblyopia or spinal spastic ataxia may be added to the clinical picture

Although neuropathy is commonplace in Wernicke s disease the advanced stages of beriberi heart disease are rarely observed There are how

troublesome they consist mainly of numbness prickly feelings coldness deadness tenderness of the calf and plantar musculature or unusual sensitivity to contact In a minority of patients pain and paresthesias constitute the chief complaints The pain may take the form of a dull constant ache in the feet sometimes of the entire leg often the *pains are sharp and lancinating momentary in* duration quite like the lightning pains of tabes dorsalis Complaints of coldness are common but they are purely subjective the feet feeling quite warm to touch Much more distressing and incapacitating are the "burning" feelings and sensations of heat usually these affect the soles and less frequently the dorsal aspects of the feet as well They fluctuate in intensity or may be clearly intermittent in nature Characteristically a patient afflicted with pains and paresthesias suffers not one but all of the symptoms enumerated Although the painful symptoms may arise spontaneously they are made much worse by any contact with the feet The amount of pressure required to produce discomfort varies in severe cases the patient cannot bear to have the bedclothes touch his feet or to have the cold metal of an eating utensil touch his hands Because of these dysethesias he may be unable or unwilling to walk despite the preservation of motor power

The examination reveals varying degrees of motor *reflex* and *sensory loss* As the symptoms would suggest the signs are symmetric usually more prominent in the distal portions of the limbs and often confined to the legs The weakness varies greatly in degree It may be evident only with muscular exertion or it may take the form of a foot and wrist drop or even of a complete paralysis of the limb The deep reflexes in the legs are almost universally lost even with the mildest degrees of weakness and this is also true in the arms although occasionally the tendon reflexes are retained here despite serious loss of power in the hands In a small number of patients particularly those with pain and paresthesias the reflexes may be of greater than average briskness The sensory loss usually involves all the modalities Although one cannot adequately equate touch pain and temperature and vibratory and position sense some patients seemingly show an impairment or loss of one modality out of proportion to the others There is no sharp border between normal and impaired sensation the sensory loss which is most profound distally shades off gradually the transition to normal sensation *occurring over a long vertical extent* of the limb

As a rule only the limbs are affected and the abdominal thoracic and bulbar musculature are intact In some instances of Oriental beriberi, sensory loss has reportedly involved the face and abdomen as well Tinnitus vertigo nerve deafness aphonia due to vocal cord paralysis (particularly in infants) and retrobulbar neuropathy may also complicate beriberi in rare instances The relation of these disturbances to beriberi has been a point of contention that cannot be settled with finality since the specific cause of neither is known Far *more frequently they are engrafted on the syn*drome of ataxia and burning tender feet and are therefore appropriately considered as a part of Strachan's syndrome

The *spinal fluid* in the nutritional neuropathies is usually normal although an occasional case may show a slight elevation of the protein content The normal spinal fluid may be helpful in distinguishing the rapidly evolving form of nutritional neuropathy from infectious polyneuritis

Recovery is invariably a slow process In the mildest cases there may be considerable restoration of motor power in a few weeks in the severest forms several weeks may pass before even the first signs of recovery become manifest and up to a year before the patient is able to walk unaided Recovery in severely affected patients is often incomplete and they may be left with some weakness of the feet and an absence of the knee and ankle jerks The development of contractures due to inadequate physiotherapy prolongs convalescence

Pathologic Changes *Pathologically* nutritional neuropathy is characterized by a degeneration of the peripheral nerves and in advanced cases of the anterior and posterior nerve roots The degenerative process is more intense in the distal segments than in the proximal ones Both the myelin and the axis cylinders are destroyed the former probably earlier and to a greater extent than the latter The degeneration is Wallerian in type in some places whereas in others there may be segments of nerve in which the myelin is lost and the bare axis cylinders remain (the segmental demyelination of Gombault) Dorsal root ganglion cells may be lost to variable extent and the anterior horn cells of the spinal cord show an axonal reaction The latter change is probably secondary to the axis cylinder damage in the anterior roots and peripheral nerves

The "Burning Feet" Syndrome The term *burning feet* is frequently applied to a state in which pain in the extremities is the outstanding symptom and in which the advanced signs of neuropathy may be absent It is doubtful whether this syndrome merits *classification apart from other nutritional neuropa*thies it is here considered separately out of deference to the many reports from the prisoner-of war and internment camps of the Far East In these reports the pain is variously described as tingling burning aching shooting cramplike or

chosis as is the disorganization of past memory Since the adaptation to every new situation requires the forming of new memories or at least combining new and old ones it is the defect in this function which renders the patient helpless in society and capable of performing only the most routine tasks Moreover when the patient attempts to reconstruct the past there are large gaps in the recounted material Only isolated facts are retained and these are not combined in proper chronology so that the whole is distorted Or new material may be introduced drawn from the patient s own experience and having some logical relation to the story This defect becomes obvious after the acute stage of the illness has passed and some improvement in function has occurred, and it remains the dominant disturbance in all but the few patients who make a complete recovery

In addition to the disorders of cognitive function and memory a significant proportion of patients show a *state of confusion* particularly in the early stages of their illness Such patients are quite unable to grasp their immediate situation—to recognize the examiner as a physician to appreciate that they are in the hospital the time of the day or season of the year etc They misidentify people around them and misinterpret their actions and apprehension and at times even panic may be aroused by their misinterpretations and delusions In such states as in delirium the confusion appears to depend not so much on amnesia as on a widespread perceptual disorder

Confabulation is widely regarded as a specific symptom of Korsakoff's psychosis but this is not true for it is found in many other confusional states as well Furthermore confabulation is not observed in all the patients with Korsakoff s psychosis and the diagnosis can readily be made without it

The outcome of Korsakoff s psychosis varies In a small proportion of patients complete recovery may be expected More commonly there is slow and incomplete recovery over a year or longer Depending on the severity of the residual symptoms the patient may or may not be able to lead an independent existence out of a hospital If the damage to the brain is severe permanent commitment to a psychiatric hospital is required The residual mental state is usually one in which the patient shows large gaps in memory and the inability to sort out events in their proper temporal sequence If the patient is seen for the first time during this stage the diagnosis of alcoholic deteriorated state" or organic brain syndrome due to alcohol is commonly made

The Unity of Wernicke s Encephalopathy and Korsakoff's Psychosis Several allusions have already been made to the relation between these two syndromes Clinically the majority of patients with Wernicke s disease show signs of Korsakoff's psychosis either from the time they are first seen or following a period of apathy and drowsiness Conversely the vast majority of patients with an amnestic confabulatory psychosis show the stigmas of Wernicke s disease (slight nystagmus and ataxia) even years after the onset of the illness The pathologic changes in the brain are very much the same whether the patient dies in the acute stages of Wernicke s disease or in the chronic phase of the illness when the ocular palsies have cleared and the amnestic symptoms predominate It would appear that in the nutritionally deficient alcoholic patient Wernicke s disease and Korsakoff s psychosis represent but different facets of the same disease process

Nutritional Polyneuropathy (Neuritic Beriberi)

For many years this was believed to be an exclusively Oriental disease After the First World War and particularly in the last two decades it became established that there was no essential difference clinically or pathologically between the neuropathy of beriberi and that which occurred among alcoholics in the Western Hemisphere Even the cardiovascular manifestations of beriberi have their counterpart in the alcoholic populations For these reasons alcoholic (nutritional) neuropathy and dry (neuritic) beriberi will be treated together

Symptoms and Signs The symptomatology of nutritional polyneuropathy is remarkably diverse In fact many patients are asymptomatic Only upon careful examination will the thinness of the leg muscles and loss or depression of the knee and ankle jerks or of the ankle jerks alone be detected Less frequently calf tenderness somewhat diminished muscle power in the feet and legs or a patchy blunting of pain and touch sensation over the feet and shins are also found

Patients with the manifest form of alcoholic beriberi report a variety of symptoms consisting of weakness paresthesias and sometimes pain The symptoms are usually insidious and slowly progressive although at times there may be a rapid progression in the weakness In a small but characteristic group the transition from an asymptomatic state to one of virtual paralysis occurs in a matter of several days The symptoms are at first referred to the distal portions of the limbs and progress proximally if the illness remains untreated The legs are affected earlier than the arms these are the only members of the body which are involved Only in exceptional cases may the arms be affected more severely than the legs Motor and sensory symptoms usually occur concomitantly although the patient may complain much more of one than the other Usually weakness constitutes the source of disability Sensory symptoms may however be

an acute confusional psychosis dominates the clinical picture Pellagra not only may produce insanity but occasionally may result from it because of the anorexia and refusal of food that accompany certain mental illnesses The manifestations of spinal cord involvement have not been clearly delineated perhaps because the mental state of the patients has precluded accurate testing In general they are referable to both the peripheral nerve and posterior columns as well as the lateral column predominantly the former Neuritic signs are often difficult to distinguish from affection of the posterior columns Signs such as tremors extrapyramidal rigidity sucking and grasping reflexes and coma have been ascribed to the pellagrous syndrome as have various disorders of the special senses

The distinctive *pathologic changes* in pellagra are most readily discerned in the large cells of the motor cortex, the cells of Betz which appear swollen and rounded with eccentric nuclei and loss of the Nissl particles This change was first described by Adolf Meyer as *central neuritis* and is frequently referred to as *axonal reaction* because of the similar nerve cell change which occurs most frequently in the anterior horn cells when their axones are severed It is likely that the central neuritis of pellagra is not dependent on injury to the axones of the Betz cells Rather it appears to represent a primary affection of the whole motor cell The spinal cord lesions take the form of a symmetric degeneration of the dorsal columns especially of Goll, and to a lesser extent of the pyramidal tracts The posterior column degeneration affects a specific system of fibers and is secondary to the degeneration of the posterior roots The nature of the pyramidal tract lesion in pellagra is not known one can only speculate that this change is secondary to the pyramidal cell degeneration

A spinal spastic syndrome apart from the other symptoms and signs of pellagra, may be a rare manifestation of deficiency disease The chief clinical signs are spastic weakness of the legs with absent abdominal and increased tendon reflexes clonus and extensor plantar responses These signs are usually accompanied by other signs of nutritional deficiency such as Wernicke s disease delirium and retrobulbar and peripheral neuropathy

Strachan s Syndrome

Beginning with the report of Strachan in 1888 and culminating with the recent observations among prisoners of war and civilian internees there has appeared a large number of reports about a condition which cannot be forced into the boundaries of the classical nutritional syndromes of Wernicke Korsakoff beriberi pellagra or pernicious anemia and subacute degeneration of the spinal cord When these descriptions are viewed collectively a symptom complex emerges the principal features of which are paresthesias of the feet hands trunk and even face burning tender feet impaired vision and loss of reflexes Less common features are dizziness deafness hoarseness acute myasthenia spasticity and mucocutaneous lesions Strachan was the first to describe this syndrome although he did not recognize its nutritional etiology

Strachan s syndrome is essentially a disorder of the peripheral and optic nerves Clinically sensory symptoms and signs dominate the picture in this respect the syndrome differs from beriberi Paresthesias of the extremities face and trunk painful hyperesthesia" of the feet loss of superficial and deep sensation and ataxia are the common manifestations On the other hand foot drop and muscle weakness occur very rarely A frequent associated disorder is failing vision, which may go on to complete blindness and pallor of the optic disks In general deafness and vertigo are rare complications but in some outbreaks these symptoms were so common as to earn the epithet "camp dizziness" Along with the neurologic signs there are varying degrees of stomatoglossitis corneal degeneration and genital dermatitis these mucocutaneous lesions are often spoken of together as the *orogenital syndrome* and are quite distinct from those of pellagra

There have been only a few pathologic studies of this syndrome Aside from the damage to the papillomacular bundle in the optic nerve the most consistent abnormality has been a loss of medullated fibers in each column of Goll adjacent to the midline This indicates a systematized degeneration of the central process of the bipolar sensory neurone of the lumbosacral spinal ganglions The fact that the primary sensory neurone is the chief site of disease is consistent with the predominant sensory symptomatology

Subacute Combined Degeneration of the Spinal Cord and Brain

Subacute combined degeneration of the spinal cord the neurologic component of pernicious anemia is due to a vitamin deficiency (vitamin B_{12}) but is clearly different from the other nutritional diseases The disease results not from the lack of vitamin B_{1} in the food but from the inability to transfer minute amounts of the vitamin across the intestinal mucosa apparently the result of a failure of gastric secretion Such "starvation in the midst of plenty" has been called *conditioned deficiency disease* The general features of pernicious anemia are fully discussed in Chap 212 here only the neurologic manifestations will be considered

Clinical Manifestations Symptoms of nervous system disease are present in 75 to 89 per cent of patients with pernicious anemia The patient first

resembling the lightning pains of tabes The pain was often very severe it was greatest at night and interfered with sleep Some patients found relief from the application of cold others only in movement The presence of associated neuritic signs was a variable matter In some patients wasting dropped foot reflex loss and sensory changes were completely wanting in a significant proportion the tendon reflexes were exaggerated but without clonus or extensor plantar responses However in other groups of patients the painful feet were but one stage in the evolution of a peripheral neuropathy characterized by tenderness of the calves reflex and sensory loss and ataxia and complicated in many cases by retrobulbar neuropathy

In alcoholic (nutritional) polyneuropathy pain is the outstanding symptom in a small group of patients however they do not constitute a distinct group in terms of their neurologic signs Pain and dysesthesia may be a prominent symptom in cases with all degrees of motor reflex and sensory loss In some cases the weakness may be slight or absent and in rare instances reflexes may be retained despite a severe "burning feet syndrome However in all cases of severe hyperesthesia even where the slightest stimulus appears intolerable there is usually sensory loss one is able by using finely graded stimuli to demonstrate an elevated threshold to painful thermal and tactile stimuli in the hyperesthetic zone The term *hyperesthetic* is therefore not well chosen it implies a heightened receptiveness of the nervous system or an increased response of the receptors to tactile and painful stimuli Actually there is an underlying sensory deficit or an elevated threshold to various stimuli once the stimulus is perceived however it may have a severely painful or unpleasant quality (hyperpathia)

Obviously the term *burning* is not particularly applicable considering the wide variety of symptoms apart from thermal dysesthesias Because of this as well as the fact that the hands may be involved the term *acrodysesthesias* or *painful extremities* is preferred by some

Although undoubtedly nutritional the specific deficiency responsible for the dysesthesias has not been clearly established The pathophysiology is likewise unknown Spillane suggests that this affection is an early stage of nutritional disturbance in the nerves to the lower limbs He draws an analogy to the burning pains produced by the interruption of conduction in large nerve fibers by rendering a limb ischemic The authors have been impressed by the similarity of the pain to causalgia and in several patients have succeeded in abolishing the pain for several hours to days by paravertebral sympathetic block These observations require confirmation

Nutritional Amblyopia

This term refers to the visual failure which occurs in nutritional disease but which is not due to a lesion of the cornea or other parts of the eye concerned with refraction The site of the lesion is most likely in the optic nerve so that the term *retrobulbar neuropathy* is a suitable synonym

Clinically the characteristic symptom is a blurring of vision for near and distant objects usually developing gradually over a period of several weeks Examination discloses a reduction in visual acuity the presence of central and centrocecal scotomas for white or colors and in some cases fundoscopic abnormalities The latter vary from a mild papillitis slight hyperemia and perhaps blurring of the disk margins to pallor of the optic disk in the most advanced cases Retinal hemorrhages may be seen occasionally These changes are always bilateral though frequently asymmetric Untreated the disease may progress to irreversible optic atrophy With nutritious diet and multiple vitamin supplements improvement occurs in all instances though to a variable extent

In this country many if not all of the cases of retrobulbar neuropathy attributed to the toxic effects of alcohol or tobacco are probably of nutritional origin Retrobulbar neuropathy may occur as the only manifestation of deficiency but far more frequently it is combined with other nutritional syndromes such as peripheral neuropathy the Wernicke Korsakoff syndrome or rarely by a spinal spastic and ataxic syndrome (Strachan s disease)

Deficiency amblyopia was particularly prevalent during the last war in the prisoner of war and civilian internment camps of the Far East Although it had previously been described in association with beriberi and pellagra the peak incidence did not coincide with that of either of these syndromes but with the mucocutaneous lesions in orogenital regions and burning feet syndromes Although the amblyopia seemed to respond best to a diet rich in riboflavin the etiologic relationship to this vitamin cannot be regarded as established

Pellagra

This discussion is concerned only with the neurologic manifestations which in themselves are extremely diverse Pellagra is essentially an encephalopathy although involvement of all parts of the nervous system has been described In the early stages of the disease the symptoms are mainly mental and may be mistaken for those of a psychoneurosis Insomnia fatigue nervousness irritability or feelings of depression are common complaints Examination may reveal retardation of mental processes and impairment of memory Sometimes

vitamin B_{12} daily is an adequate dosage in the treatment of subacute combined degeneration of the cord but in practice the amount prescribed is usually higher

The improvement in neurologic signs is quite dramatic and complete when effective therapy is instituted early after the onset of symptoms In practically all instances at least partial improvement is effected although in long standing cases often the best that can be accomplished is arrest of progression The most important factor influencing the response to treatment is the duration of the disease as measured by the duration of difficulty in walking The greatest improvement occurs in those whose difficulty in walking is of less than 3 months duration and conversely the least improvement occurs in those with difficulty in walking of longer than 2 years duration Factors of little or no importance are age sex severity arteriosclerosis hypertension and the degree of anemia Neurologic relapses during therapy are usually associated with infections and can be corrected by increasing the dose of liver extract or vitamin B_{12} All neurologic symptoms and signs may be improved extensor plantar responses are as responsive to treatment as paresthesias and loss of vibratory sense The return of absent deep reflexes is commonly observed although at times it may take longer than a year Most improvement occurs during the first 3 to 6 months of therapy but there may be continued improvement for a year or longer

Diagnosis The chief obstacle in the early diagnosis of subacute combined degeneration of the cord is the lack of parallelism between the hematologic and neurologic manifestations With the widespread use of folic acid this problem has become more acute since this drug may cause a hematologic remission for an indefinite period while the neurologic signs worsen often to an irreversible stage Other problems concern the difficulty of distinguishing between intrinsic spinal cord disease of non pernicious anemia type from posterior and lateral column disease due to pernicious anemia and of distinguishing pernicious anemia and subacute combined degeneration from other macrocytic anemias and their associated neurologic disturbances

In most instances the diagnosis can be made by utilizing the standard methods for the diagnosis of pernicious anemia (see Chap 212) the examination of the blood gastric acidity and the bone marrow These methods are of limited value when the anemia is mild or absent or when the anemia has been corrected by folic acid A therapeutic trial of vitamin B_{12} may be employed but recourse to such a procedure means that therapy must be continued indefinitely and the diagnosis may remain in doubt Under these circumstances a number of refined diagnostic aids may be employed such as the Schilling test (Chap 212) or the microbiologic assay of B_{12} utilizing the organism *Euglena gracilis*

259 DEGENERATIVE DISEASES OF THE NERVOUS SYSTEM

Edward P Richardson Jr

The term *degenerative* as applied to diseases of the nervous system is used to designate a group of disorders in which there is gradual generally symmetric relentlessly progressive wasting away of structural elements of the nervous system for reasons still unknown Many of the conditions so designated clearly depend upon abnormal genetic factors and thus appear in more than one member of the same family this general group of diseases is therefore frequently referred to as *heredodegenerative* A number of others without apparently differing in any fundamental way from the hereditary group occur only sporadically i e as isolated instances in a given family It is obvious that to call these diseases degenerative is to say that the underlying causes are as yet undetermined Sir William Gowers in 1902 suggested the now familiar term *abiotrophy* to describe them by which he meant that diseases of this class were based upon defective vital endurance of the affected parts which led to their premature death Concise and convenient as this term may be it of course tells little or nothing of the true nature of the defects It is to be assumed that the basis for these diseases must be found in *some* disorder of the metabolism of the parts involved

Within relatively recent times there has been some elucidation of the nature of a number of nervous disorders which in their symmetric distribution and graduallly progressive course resemble the class of diseases under discussion Examples of these are the deficiency diseases such as subacute com

notices general weakness and paresthesias consisting of tingling pins and needles feelings or other vaguely described sensations The paresthesias tend to be constant to progress steadily and to be the source of much distress They are localized to the distal parts of all four limbs in a symmetric distribution the lower extremities usually being involved before the upper ones As the illness progresses stiffness and weakness of the limbs develop especially of the legs and combined with a defect in postural sensation produce a weak unsteady gait and awkwardness of the limbs If the disease remains untreated an ataxic paraplegia with variable degrees of spasticity and contracture may develop

Early in the course of the illness when only paresthesias are present there may be no objective signs Later the neurologic examination may indicate a disturbance of all parts of the nervous system but mainly of the posterior and lateral columns of the spinal cord Loss of vibration sense is by far the most consistent sign it is more pronounced in the legs than in the arms and frequently it extends over the trunk Position sense is involved somewhat less frequently Isolated instances of loss of superficial sensation below a segmental level on the trunk do occur implicating the spinothalamic tracts but such a finding should always suggest the possibility of some other disease of the spinal cord More commonly the defect of cutaneous sensation takes the form of a mild blunting of touch pain and temperature sensation over the limbs in a distal distribution

Examination of the motor system discloses loss of power spasticity changes in the tendon reflexes clonus and extensor plantar responses These signs are practically limited to the legs At first the patellar and Achilles reflexes are found to be diminished in activity as frequently as they are increased and may even be absent With treatment the reflexes may return to normal or even become hyperactive Gait may be predominantly ataxic or spastic usually both The nervous system involvement in subacute combined degeneration is characteristically although not always symmetric A definite asymmetry of motor or sensory findings maintained over a period of weeks or months should always cast doubt on the diagnosis of subacute combined degeneration of the spinal cord

Mental signs are frequent ranging from irritability apathy somnolence suspiciousness and emotional instability to a marked confusional or depressive psychosis or intellectual deterioration Signs of visual impairment are distinctly rare when present they take the form of centrocecal scotomas If involvement of the optic nerve is severe optic atrophy may occur

Neuropathologic Changes The pathologic process takes the form of diffuse although uneven degeneration of the white matter There are multiple foci of spongy degeneration often in relation to small blood vessels The myelin sheaths and the axis cylinders are both affected the former perhaps earlier and to a greater extent than the latter There is relatively little fibrous gliosis in the early lesions but in the older ones so often seen in treated cases gliosis is pronounced The changes begin in the posterior columns of the thoracic cord and spread from this region up and down the cord as well as forward into the lateral columns The lesions are not limited to specific systems of fibers within the posterior and lateral funiculi but are scattered irregularly through the latter

The paresthesias impairment of vibratory and position sense ataxia and the Romberg sign are due to affection of posterior columns and lesions here may also account for loss of tendon reflexes Weakness spasticity increased tendon reflexes and Babinski signs depend on involvement of the pyramidal tracts in the lateral columns The spinothalamic tract may be involved in the pathologic process which explains the occasional clinical finding of loss of pain and temperature sensation at a segmental level on the trunk In advanced forms of the disease similar pathologic changes may occur in the white matter of the brain Instances of degenerative lesions of the optic nerves have also been verified at necropsy

There is no unanimity of opinion regarding the occurrence of lesions in the peripheral nerves in pernicious anemia The clinical evidence is stronger than the pathologic and the existence therefore of disease in the spinal roots and nerves is largely inferential It has been suggested that reversibility of neurologic signs is indicative of peripheral nerve involvement The distal and symmetric blunting to pain touch and temperature that occurs in many cases is certainly a point in favor of peripheral nerve disease It has been shown that there is a loss of myelin in peripheral nerves but there is no convincing evidence that axis cylinders are affected

Aside from the characteristic laboratory findings of pernicious anemia (see Chap 212) there are few laboratory tests that are specifically helpful in the diagnosis of the nervous system disorder The *spinal fluid* is usually normal although occasionally there may be a slight elevation of the protein content

Efficacy of Liver and Vitamin B_1 At first it was believed that the spinal cord and blood changes were due to separate deficiencies and for this reason treatment with liver extract was supplemented with crude liver However there is now sufficient evidence that the response to vitamin B_{12} alone is in all ways comparable to that from refined liver extract or crude liver It has been suggested that the equivalent of 1 μg of parenterally administered

A number of other examples could be cited (e g Friedreich s ataxia) in which certain related groups of neuronal systems disintegrate For this reason a number of the degenerative diseases have been designated as system diseases ("progressive cerebrospinal system atrophies"—Spatz) and their generally hereditary nature has been emphasized It must be realized however that disease processes of other kinds may likewise result in remarkably selective destructive effects as shown by the special vulnerability of the larger pyramidal cells of the hippocampus to hypoxia of the Purkinje cells of the cerebellum to hypoxia and hyperthermia and other similar examples On the other hand a number of other conditions can be cited in which classification with the degenerative group is fully justified and yet the disease process acts diffusely without restriction to particular systems—as for instance with Alzheimer s disease and the leukodystrophies Nonetheless with these reservations predominant affection of particular neuronal systems remains an important distinguishing feature

As a general rule it is the nervous system that is primarily affected and any disease process that may be found in other organs is secondary or unrelated Metabolic and biochemical investigations have failed to disclose any systemic disorder to which the neurologic changes can be attributed Since the pathologic process in the nervous system is one of slow involution of nerve cell bodies or their prolongations as nerve fibers without intense tissue reaction examination of the cerebrospinal fluid as would be expected shows at most a slight elevation of protein without abnormalities in pressure cell count or in other constituents Furthermore since these diseases result invariably in tissue loss rather than in new tissue formation (as with neoplastic or inflammatory conditions) x ray visualization of the ventricular system or subarachnoid space shows either no change or an enlargement of these compartments These negative laboratory findings thus help to distinguish the conditions under discussion from the other large classes of progressive disease of the nervous system—tumors and infections

CLASSIFICATION

Since etiologic classification is impossible the separation of the degenerative diseases into a number of syndromes rests on descriptive criteria based largely upon pathologic anatomy but to some extent on clinical aspects as well In the terms currently used to designate these morbid entities the names of a number of distinguished neurologists and neuropathologists are commemorated A useful way of keeping in mind the various disease states is to group them according to the outstanding clinical features that may be found in an actual case The following classification intended to be of practical help to the physician is based on such a plan

- I Conditions in which dementia is an outstanding feature in the absence of other striking neurologic signs
  - A Diffuse cerebral atrophy
    - 1 Senile dementia
    - 2 Alzheimer s disease
  - B Pick s disease (circumscribed cerebral atrophy)
- II Conditions in which dementia is strikingly combined with other neurologic signs
  - A Principally in adults
    - 1 Huntington s chorea
    - 2 Cerebrocerebellar degeneration
    - 3 Jakob Creutzfeldt disease
  - B In children and adults
    - 1 Amaurotic family idiocy (neuronal lipoidoses)
    - 2 Leukodystrophy
    - 3 Familial myoclonus epilepsy
    - 4 Hallervorden Spatz disease
    - 5 Wilson s hepatolenticular degeneration Westphal Strumpell pseudosclerosis
- III Conditions chiefly manifested by abnormalities of posture or involuntary movements
  - A Paralysis agitans (Parkinson s disease)
  - B Dystonia musculorum deformans (torsion dystonia)
- IV Conditions chiefly manifested by ataxia
  - A Cerebellar degenerations of late life
  - B Spinocerebellar degenerations (Friedreich s ataxia Marie s hereditary ataxia)
- V Conditions with outstanding muscular weakness and wasting
  - A Without sensory changes
    - 1 In adults
      - a Motor system disease
      - b Amyotrophic lateral sclerosis
      - c Progressive muscular atrophy
      - d Progressive bulbar palsy
      - e Primary lateral sclerosis
    - 2 In children or young adults
      - a Infantile muscular atrophy (Werdnig Hoffmann disease amyotonia congenita)
      - b Hereditary spastic paraplegia
  - B With sensory changes
    - 1 Syringomyelia (and syringobulbia)
    - 2 Progressive neural muscular atrophy
      - a Peroneal muscular atrophy (Charcot Marie Tooth)
      - b Hypertrophic interstitial neuropathy (Déjerine Sottas)
    - 3 Miscellaneous forms of chronic progressive neuropathy
- VI Conditions chiefly manifested by visual loss
  - A Hereditary optic atrophy (Leber)
  - B Pigmentary degeneration of the retina (retinitis pigmentosa)

A number of other examples could be cited (e g Friedreich s ataxia) in which certain related groups of neuronal systems disintegrate For this reason a number of the degenerative diseases have been designated as *system diseases* (progressive cerebro spinal system atrophies"—Spatz) and their generally hereditary nature has been emphasized It must be realized however that disease processes of other kinds may likewise result in remarkably selective destructive effects as shown by the special vulnerability of the larger pyramidal cells of the hippocampus to hypoxia of the Purkinje cells of the cerebellum to hypoxia and hyperthermia and other similar examples On the other hand a number of other conditions can be cited in which classification with the degenerative group is fully justified and yet the disease process acts diffusely without restriction to particular systems—as for instance with Alzheimer s disease and the leukodystrophies Nonetheless with these reservations predominant affection of particular neuronal systems remains an important distinguishing feature

As a general rule it is the nervous system that is primarily affected and any disease process that may be found in other organs is secondary or unrelated Metabolic and biochemical investigations have failed to disclose any systemic disorder to which the neurologic changes can be attributed Since the pathologic process in the nervous system is one of slow involution of nerve cell bodies or their prolongations as nerve fibers without intense tissue reaction examination of the cerebrospinal fluid as would be expected shows at most a slight elevation of protein without abnormalities in pressure cell count or in other constituents Furthermore since these diseases result invariably in tissue loss rather than in new tissue formation (as with neoplastic or inflammatory conditions) x ray visualization of the ventricular system or subarachnoid space shows either no change or an enlargement of these compartments These negative laboratory findings thus help to distinguish the conditions under discussion from the other large classes of progressive disease of the nervous system—tumors and infections

CLASSIFICATION

Since etiologic classification is impossible the separation of the degenerative diseases into a number of syndromes rests on descriptive criteria based largely upon pathologic anatomy but to some extent on clinical aspects as well In the terms currently used to designate these morbid entities the names of a number of distinguished neurologists and neuropathologists are commemorated A useful way of keeping in mind the various disease states is to group them according to the outstanding clinical features that may be found in an actual case The following classification intended to be of practical help to the physician is based on such a plan

I Conditions in which dementia is an outstanding feature in the absence of other striking neurologic signs
- A Diffuse cerebral atrophy
  - 1 Senile dementia
  - 2 Alzheimer s disease
- B Pick s disease (circumscribed cerebral atrophy)

II Conditions in which dementia is strikingly combined with other neurologic signs
- A Principally in adults
  - 1 Huntington s chorea
  - 2 Cerebrocerebellar degeneration
  - 3 Jakob Creutzfeldt disease
- B In children and adults
  - 1 Amaurotic family idiocy (neuronal lipoidoses)
  - 2 Leukodystrophy
  - 3 Familial myoclonus epilepsy
  - 4 Hallervorden Spatz disease
  - 5 Wilson s hepatolenticular degeneration Westphal Strumpell pseudosclerosis

III Conditions chiefly manifested by abnormalities of posture or involuntary movements
- A Paralysis agitans (Parkinson s disease)
- B Dystonia musculorum deformans (torsion dystonia)

IV Conditions chiefly manifested by ataxia
- A Cerebellar degenerations of late life
- B Spinocerebellar degenerations (Friedreich s ataxia Marie s hereditary ataxia)

V Conditions with outstanding muscular weakness and wasting
- A Without sensory changes
  - 1 In adults
    - *a* Motor system disease
    - *b* Amyotrophic lateral sclerosis
    - *c* Progressive muscular atrophy
    - *d* Progressive bulbar palsy
    - *e* Primary lateral sclerosis
  - 2 In children or young adults
    - *a* Infantile muscular atrophy (Werdnig Hoffmann disease amyotonia congenita)
    - *b* Hereditary spastic paraplegia
- B With sensory changes
  - 1 Syringomyelia (and syringobulbia)
  - 2 Progressive neural muscular atrophy
    - *a* Peroneal muscular atrophy (Charcot Marie Tooth)
    - *b* Hypertrophic interstitial neuropathy (Dejerine Sottas)
  - 3 Miscellaneous forms of chronic progressive neuropathy

VI Conditions chiefly manifested by visual loss
- A Hereditary optic atrophy (Leber)
- B Pigmentary degeneration of the retina (retinitis pigmentosa)

CONDITIONS IN WHICH DEMENTIA ALONE PREDOMINATES

In the disease entities about to be discussed the clinical picture is dominated by gradual loss of intellectual capacities i e by *dementia* Other neurologic abnormalities except in the terminal stages are absent or relatively insignificant (For further discussion of dementia including its clinical evaluation Chap 36 should be consulted)

Diffuse Cerebral Atrophy Senile Dementia, Alzheimer's Disease

Some degree of shrinkage in size and weight of the brain "atrophy" has been shown to be the inevitable accompaniment of advancing age In many instances this is of no clinical significance and there are many very old people who remain alert and perceptive with keen intellect to the end Nevertheless severe degrees of diffuse cerebral atrophy are always associated with some evidence of dementia When these changes occur in old age (and the definition of when old age begins is largely a subjective one) it is usual to speak of *senile dementia* That this is a fairly frequent condition is common experience Much more infrequent is a pathologically identical *progressive dementia* with diffuse brain atrophy coming on well before the senile period a *presenile dementia* This condition classically described in 1906 by Alois Alzheimer has since come to be generally known as *Alzheimer's disease* The distinction between the two conditions is purely a clinical one pathologically they differ only in that the characteristic abnormalities tend to be more severe and widespread in cases beginning at an earlier age than the senile period It is to be presumed that the basic underlying derangement is the same but that its effects differ somewhat depending on the age of the patient

Pathology The brain presents typically a generally shrunken appearance with atrophy of the convolutions and symmetric enlargement of the lateral and third ventricles Frequently these changes are especially pronounced in the frontal lobes Microscopically there is widespread loss of nerve cells most apparent in the cerebral cortex with secondary astrocytic glial proliferation In addition two types of lesions give this disease process its distinctive character (1) Scattered throughout the cerebral cortex are microscopic spherical deposits of amorphous material most easily seen with silver staining methods They are the so called senile plaques which have been known for some 65 years and which are generally considered to be an abnormal deposition or precipitation of material in the brain tissue rather than the remains of diseased nerve cells Despite numerous investigations and an extensive literature devoted to them their origin and nature still remain uncertain The other characteristic histopathologic feature is the *Alzheimer fibrillary change* in nerve cells This striking abnormality first clearly described by Alzheimer in his publication on presenile dementia consists of the presence within the cytoplasm of thick fiber like strands of silver staining material often in the form of loops coils or tangled masses This is a cytologic derangement which apparently ends in death of the cell for clumps of these fibrils can often be seen even after the cell bodies within which they arose have disappeared Despite ingenious attempts to explain them (cf von Braunmuhl 1957) the *true nature and meaning of these remarkable appearances have yet to be learned* Senile plaques and fibrillary changes occur most numerously in the cortex and are widely distributed although most frequent of all in the frontal lobes and hippocampal gyri They have been encountered in all regions of the brain but rarely if ever in the spinal cord Abundant pathologic evidence clearly establishes that the *neuropathologic alterations just described* are not related to vascular disease or to any known systemic disorder

Clinical Aspects This condition has been described as occurring during every age period even in childhood although it is most frequently a disease of the later decades of life Although a number of well-documented familial cases exist there is not sufficient evidence to indicate that this is truly an hereditary disorder in practice most cases are seen as sporadic instances The onset is insidious and subtle with changes first most noticeable in the faculties of memory for recent happenings and for over all judgment of situations Emotional disturbances such as depression or anxiety states or odd unpredictable quirks of behavior may be salient features in the early stages Progression is very slow and gradual and unless the condition is earlier brought to a close by the effects of advanced age it may linger on for some 10 to 15 years

In the milder cases including those of the senile period the noteworthy features are those of simple dementia as described in Chap 36 More atypical disorders of thought and intellect including aphasia apraxia like disturbances and abnormalities of space perception may be encountered in the more severe forms such as are seen in younger individuals Neurologic examination characteristically discloses no other abnormalities Additional investigative procedures including the usual blood and cerebrospinal fluid determinations and electroencephalography do not yield any conclusive or pertinent data The enlargement of the ventricular system and subarachnoid space resulting from the diffuse brain atrophy can be demonstrated by pneumoencephalography

otherwise no characteristic roentgenographic findings are seen During the course of the illness occasional convulsive seizures may occur but they do not always accompany the disorder Terminally a state of total helplessness is reached and the patient dies from intercurrent disease Usually long before the end institutional care is necessary

Differential Diagnosis The diagnosis is made by excluding by means of the usual clinical methods other conditions that may produce dementia The concern of the physician must naturally be to make certain that there is no condition which may improve with treatment such as tumor chronic subdural hematoma infection (e g syphilitic or tuberculous meningoencephalitis) or well defined metabolic or deficiency disease Ordinarily the clinical picture of very gradually progressive dementia without definite focal neurologic signs without evidence of increased intracranial pressure pleocytosis or significantly raised protein in the cerebrospinal fluid in the presence of otherwise good general health is in itself sufficient to lead unmistakably to the diagnosis of a diffuse degenerative disease of the brain which is almost always of the type under discussion In the presence of such evidence it should not be necessary to resort to more complicated procedures to make this diagnosis However it is usual since so much depends on it to ensure the accuracy of the diagnosis by pneumoencephalography

Pick's Disease (Circumscribed Cerebral Atrophy)

This remarkable form of cerebral atrophy was first brought to attention by a series of publications by Arnold Pick in Prague around the turn of the century In the differential diagnosis of dementia in the presenile period it is usually mentioned in the same breath with Alzheimer's disease however it is an extremely rare condition in comparison with diffuse cerebral atrophy of the Alzheimer type

Pathology So striking are the gross pathologic changes in the brain that in typical cases the diagnosis can be made at a glance One sees severe atrophy of the anterior portions of the frontal and temporal lobes and there is a curiously sharp line of demarcation between the atrophied portions and the remainder of the brain which appears normal or nearly so In some cases the frontal atrophy is more prominent in others the temporal lobes are more severely involved in general both regions are affected Not infrequently the process extends to the Rolandic and parietal regions but the occipital lobes invariably are spared In many of the reported cases the changes have been considerably more pronounced on one side of the brain than the other an exception to the general rule of symmetry in degenerative nervous disease but bilaterality is the rule Characteristically there likewise are atrophic changes in a number of subcortical structures caudate nucleus putamen thalamus and substantia nigra and in the descending frontopontine fiber system In the diseased regions there is local destruction of central and convolutional white matter out of proportion to the degree of loss of nerve cell bodies in corresponding areas of the cortex this finding has led to the supposition that it is the peripheral axonal processes of the nerve cells together with their myelin sheaths which atrophy first i e that there is a gradual dying back of the neurone from the periphery to the center A noteworthy histologic feature of this condition is the occurrence of numerous swollen "ballooned out" nerve cells in the atrophic regions a finding which has been interpreted as an axonal reaction or retrograde cell change secondary to the involutional process in the periphery Another frequently encountered cell change is the occurrence of spherical intracytoplasmic inclusions that stain deeply with silver impregnation methods the significance of this remains unexplained The peculiarly selective nature of the degenerative process in Pick's disease has led to its pathologic classification with the system diseases although not all observers adhere to this view The distribution of the brain atrophy does not correspond in any way with territories of vascular supply and it is to be presumed that the condition is totally unrelated to disorders of cerebral circulation

Clinical Aspects The differentiation during life between Alzheimer's and Pick's disease is difficult and is largely of academic importance Early dilapidation of personality with relative preservation of such intellectual faculties as memory and gross reasoning ability are considered to be particularly characteristic of Pick's disease also early involvement of areas related to language function in the posterior frontal and anterior temporal regions of the dominant cerebral hemisphere may lead to pronounced aphasia The disease is one of adult years especially of the presenile period (with onset at age fifty to sixty) A considerable number of cases with earlier onset have been reported (the youngest at twenty two) in these the condition tends to be somewhat more severe than in older individuals as in Alzheimer's disease Familial occurrence is on record in a number of instances Progression is slow and relentless with an average duration of about 7 years

Differential Diagnosis The considerations noted above with respect to Alzheimer's disease apply to Pick's disease as well The circumscribed frontotemporal atrophy can at times be demonstrated by pneumoencephalography

CONDITIONS COMBINING DEMENTIA WITH OTHER NEUROLOGIC SIGNS

Huntington s Chorea (Chronic Progressive Hereditary Chorea)

This condition which genetically follows the pattern of a mendelian dominant was classically described in 1872 by George Huntington who with his father and grandfather both physicians observed cases in members of a family living near his home in Long Island Unmistakable in its typical form the affliction combines progressive dementia with bizarre involuntary movements and odd postures Atypical cases have also been recognized (see below) but in general the disorder runs true to form

Pathology The brain has a generally atrophic appearance especially noticeable in the frontal lobes Particularly characteristic of this condition is severe bilateral atrophy of the caudate nucleus which becomes flattened and concave instead of projecting as a convex rounded eminence into the anterior horn of the lateral ventricle The putamen likewise is shrunken although not to the same degree as the caudate nucleus The globus pallidus is generally affected to some degree but less severely than the caudate nucleus and putamen Microscopically the affected regions show severe nerve cell loss with corresponding reactive glial changes Small nerve cells appear to be more affected than the large The disease process may likewise involve the thalamus subthalamic nucleus (corpus Luysii) and dentate nucleus of the cerebellum Other portions of the nervous system are generally spared and there are as a rule no characteristic visceral lesions

Clinical Aspects This distressing condition generally makes its appearance in early to middle adult years in what ordinarily would be the most effective and productive period of a person s existence Its typically hereditary nature has been emphasized but it is not at all rare for sporadic cases to occur The involuntary movements (bizarre grimacing respiratory irregularity faulty articulation of speech and irregular arrhythmic unpatterned movements of the limbs which impart to the gait a peculiar dancing quality) tend to be less quick and more athetoid than in Sydenham s chorea (see Chap 26) Occasional cases have been reported which on genealogic and pathologic grounds must be classified with Huntington s chorea and yet have shown progressive rigidity rather than choreiform movements As a general rule dementia runs parallel with the motor disorder but occasionally it may appear before chorea or is lacking altogether The advance of the disease is slow with increasing disability from the involuntary movements and the mental changes and is terminated after many years by death from intercurrent infection or not rarely by suicide

Differential Diagnosis There is no difficulty in the recognition of typical cases The relatively late onset progressive course dementia and lack of association with rheumatic fever help to exclude Sydenham s chorea Differentiation from hepatolenticular degeneration (Wilson s disease) which may display similar clinical changes is made by the absence in Huntington s chorea of liver disease or corneal Kayser Fleischer rings and of the characteristic biochemical abnormalities (increased copper excretion aminoaciduria) Sporadic cases of choreiform movements beginning in middle or late life may present a difficult problem in exact diagnosis The occasional cases of violent choreiform movements produced by vascular lesions classically in the subthalamic region are characterized by sudden onset unilateral distribution (hemiballismus) and a tendency to improve after a period of initial severity Virus encephalitis may occasionally be associated with choreiform movements acute development fever and pleocytosis in the cerebrospinal fluid help in recognizing such cases which can further be identified by appropriate virologic studies Although it occurs rarely self limited chorea may appear in older people without identifiable cause

Cerebrocerebellar Degeneration

The progressive cerebellar degenerations of late life and some cases of spinocerebellar degeneration may be accompanied by significant dementia the pathologic basis for which is not always easily demonstrated These disorders are dealt with more fully below in the section devoted to conditions manifested by ataxia

Jakob Creutzfeldt Disease

This designation serves to set apart a group of cases in which relatively rapidly progressive widespread neuronal degeneration occurs in adult life The original descriptions were by H G Creutzfeldt (1920) and A M Jakob (1921 and later) Since then additional studies of similar cases by a number of authors have led to the emergence of a more or less well defined clinicopathologic syndrome within which there is however considerable variability both clinically and pathologically Although most cases occur sporadically hereditary incidence is now clearly established in one family on record

Pathology Although gray matter structures at all levels may be involved the disease often affects most severely the cerebral cortex where it results in devastating neuronal destruction and intense reactive glial changes In places the cortex may be reduced to a network of astroglial fibers almost devoid of nerve cells to which the term *status*

spongiosus has been applied The additional nerve cell loss in the corpus striatum and anterior horns of the spinal cord led to the application of the term *corticostriatospinal degeneration* to this condition by S A K Wilson (1940) Much more circumscribed distribution of what apparently is the same disease process has been described in cases with principally occipitoparietal localization by Heidenhain (1949) and Meyer Leigh and Bagg (1954) Evidence for an inflammatory process is lacking There are no significant vascular lesions and no relevant changes in other organs

Clinical Aspects Most of the cases described have begun in middle age or later but the disorder may occur in young adults As might be expected from the variable distribution of the pathologic effects no uniform clinical picture is encountered but common to all cases is a rapid deterioration of mental powers to which a delirious state may be superadded Additional neurologic manifestations include variable rigidity myoclonic jerks tremors unsteadiness of stance and ataxia of gait and slurring of speech Deep reflexes may be exaggerated normal or absent the plantar reflex is usually bilaterally of extensor type (Babinski sign) In the variety originally described by Heidenhain with severest changes in the occipital lobes significant impairment or loss of vision is an early sign Defective swallowing and stupor or coma usher in the end The total course of the illness is generally less than a year from onset and may be confined to a few weeks or months the longest reported duration is 3¼ years Laboratory investigations including cerebrospinal fluid examination disclose no remarkable findings

Differential Diagnosis When syphilis or other infection has been excluded by appropriate blood and cerebrospinal fluid examinations and serologic tests and the possibility of an overwhelming intoxication has been eliminated no treatable condition remains with which this rare disorder could be confused The florid mental and neurologic changes are unlike any syndrome encountered with vitamin B deficiency A rather similar picture may be met in occasional cases of rapidly growing infiltrating glioma multiple carcinoma metastases virus encephalitis or diffuse abnormality of neuronal or myelin lipid metabolism (see below) The frequent combination of arrhythmic myoclonus and dementia places this disease along with "inclusion body" and sclerosing encephalitis and retinocerebral lipoidosis (Tay Sachs disease) as causes of myoclonic dementia Ultimately the diagnosis depends on pathologic examination

Amaurotic Family Idiocy and Other Lipoidoses

The conditions here to be considered differ from other heredodegenerative disorders in that the underlying biochemical abnormality is better defined They are characterized by a more or less widespread derangement of lipid metabolism which results in abnormal accumulations of lipids in the cytoplasm of cells of the nervous system and often of other organs as well (For information relating to the problem of the lipoidoses in general Chap 98 should be consulted) This process leads to abnormal function and eventually death of the affected nerve cells There is ample evidence for hereditary transmission of these disorders the basis for which is presumed to be a genetically determined abnormality of enzymes concerned with intracellular lipid metabolism What specific enzymes are affected and the exact details of the biochemical derangement have yet to be learned although considerable progress has been made in identifying the lipids involved As far as is known these substances are not foreign to the body or even to the cells in which they accumulate but instead are normally present there but in much smaller quantities No single entirely satisfactory term under which to classify these neurologic disorders has become generally accepted That most frequently encountered in the literature is *amaurotic family idiocy* which cannot however be accurately applied to cases of the disorder without blindness (amaurosis) or mental defect severe enough to be called idiocy Cerebromacular or retinocerebral" degeneration focuses too much attention on the macula or retina to be entirely satisfactory Probably a general name such as lipoidoses of the nervous system" would be the least objectionable lacking though it is in picturesqueness and appeal to the imagination

Special Clinical Types The general type known as amaurotic family idiocy can be further subdivided into varieties which differ from one another in age of onset and extent and location of the pathologic process Thus there are recognized

Tay Sachs Disease This classic form occurs in infants and has extremely widespread involvement including prominent retinal changes (macular cherry red spot) and a rapid progression of impaired motor control of trunk and limbs hypotonia with retained reflexes or mild spasticity seizures and impaired vision usually resulting in death by the third year of life

Late Infantile Form (Bielschowsky) This disease has a more chronic course and results in optic atrophy rather than macular cherry red spot spastic or hypotonic weakness of the limbs cerebellar ataxia tremor and other abnormalities of posture and movement seizures and mental deterioration Death usually occurs by the tenth or twelfth year

Juvenile Form (Spielmeyer II Vogt) Here the onset is still later and the course is prolonged (6 to 7 years or more) with a tendency to pigmentary

CONDITIONS COMBINING DEMENTIA WITH OTHER NEUROLOGIC SIGNS

Huntington's Chorea (Chronic Progressive Hereditary Chorea)

This condition which genetically follows the pattern of a mendelian dominant was classically described in 1872 by George Huntington who with his father and grandfather both physicians observed cases in members of a family living near his home in Long Island Unmistakable in its typical form the affliction combines progressive dementia with bizarre involuntary movements and odd postures Atypical cases have also been recognized (see below) but in general the disorder runs true to form

Pathology The brain has a generally atrophic appearance especially noticeable in the frontal lobes Particularly characteristic of this condition is severe bilateral atrophy of the caudate nucleus which becomes flattened and concave instead of projecting as a convex rounded eminence into the anterior horn of the lateral ventricle The putamen likewise is shrunken although not to the same degree as the caudate nucleus The globus pallidus *is generally affected to some degree but less severely* than the caudate nucleus and putamen Microscopically the affected regions show severe nerve cell loss with corresponding reactive glial changes Small nerve cells appear to be more affected than the large The disease process may likewise involve the thalamus subthalamic nucleus (corpus Luysii) and dentate nucleus of the cerebellum Other portions of the nervous system are generally spared and there are as a rule no characteristic visceral lesions

Clinical Aspects This distressing condition generally makes its appearance in early to middle adult years in what ordinarily would be the most effective and productive period of a person's existence Its typically hereditary nature has been emphasized but it is not at all rare for sporadic cases to occur The involuntary movements (bizarre grimacing respiratory irregularity faulty articulation of speech and irregular arrhythmic unpatterned movements of the limbs which impart to the gait a peculiar dancing quality) tend to be less quick and more athetoid than in Sydenham's chorea (see Chap 26) Occasional cases have been reported which on genealogic and pathologic grounds must be classified with Huntington's chorea and yet have shown progressive rigidity rather than choreiform movements As a general rule dementia runs parallel with the motor disorder but occasionally it may appear before chorea or is lacking altogether The advance of the disease is slow with increasing disability from the involuntary movements and the mental changes and is terminated after many years by death from intercurrent infection or not rarely by suicide

Differential Diagnosis There is no difficulty in the recognition of typical cases The relatively late onset progressive course dementia and lack of association with rheumatic fever help to exclude Sydenham's chorea Differentiation from hepatolenticular degeneration (Wilson's disease) which may display similar clinical changes is made by the absence in Huntington's chorea of liver disease or corneal Kayser Fleischer rings and of the characteristic biochemical abnormalities (increased copper excretion aminoaciduria) Sporadic cases of choreiform movements beginning in middle or late life may present a difficult problem in exact diagnosis The occasional cases of violent choreiform movements produced by vascular lesions classically in the subthalamic region are characterized by sudden onset unilateral distribution (hemiballismus) and a tendency to improve after a period of initial severity Virus encephalitis may occasionally be associated with choreiform movements acute development fever and pleocytosis in the cerebrospinal fluid help in recognizing such cases which can further be identified by appropriate virologic studies Although it occurs rarely self limited chorea may appear in older people without identifiable cause

Cerebrocerebellar Degeneration

The progressive cerebellar degenerations of late life and some cases of spinocerebellar degeneration may be accompanied by significant dementia the pathologic basis for which is not always easily demonstrated These disorders are dealt with more fully below in the section devoted to conditions manifested by ataxia

Jakob Creutzfeldt Disease

This designation serves to set apart a group of cases in which relatively rapidly progressive widespread neuronal degeneration occurs in adult life The original descriptions were by H G Creutzfeldt (1920) and A M Jakob (1921 and later) Since then additional studies of similar cases by a number of authors have led to the emergence of a more or less well defined clinicopathologic syndrome within which there is however considerable variability both clinically and pathologically Although most cases occur sporadically hereditary incidence is now clearly established in one family on record

Pathology Although gray matter structures at all levels may be involved the disease often affects most severely the cerebral cortex where it results in devastating neuronal destruction and intense reactive glial changes In places the cortex may be reduced to a network of astroglial fibers almost devoid of nerve cells to which the term *status*

superficial resemblance to Schilder's disease (encephalitis periaxialis diffusa) which is best considered as a particular form of multiple sclerosis *in fact* the leukodystrophies have frequently been grouped together as *familial Schilder's disease* The best evidence at present indicates however that the leukodystrophies represent disorders of the metabolism of the myelin sheath lipids and thus as has been frequently pointed out are most closely related to the neuronal lipoidoses previously considered The leukodystrophies can be further classified on the basis of histopathologic and histochemical differences into a number of subtypes which are considered below

Pathology The distinguishing feature is diffuse symmetric breakdown of the white matter of the cerebral hemispheres in which as a rule axones suffer damage to approximately the same degree as the myelin sheaths Also characteristic is the presence within the devastated regions of lipid breakdown products of the myelin sheaths which show distinct histochemical differences from the lipid products encountered in virtually all other destructive processes of myelin (such as infarction traumatic necrosis secondary fiber tract degeneration the demyelinative lesions of multiple sclerosis or Schilder's disease etc) In startling contrast to the extensive white matter lesions is the relative intactness of the nerve cell bodies

Metachromatic Leukoencephalopathy In a large group of cases the lipid breakdown products display the staining reaction called *metachromasia* to a degree and intensity encountered in no other nervous system disease In several cases myelin at every level in the central and peripheral nervous system has shown this abnormality and engorgement of nerve cell bodies with similar metachromatic lipid has regularly been found in anterior horn cells of the spinal cord dentate nuclei of the cerebellum and in some of the nuclei of the brain stem and basal ganglions but oddly enough not in the cerebral cortex The appearance of such cells is strikingly reminiscent of that in conditions such as amaurotic family idiocy (see above) but the location and the histochemical behavior of the involved cells are different The chemical nature of this metachromatic lipid which has also been found by several observers in Kupffer cells of the liver and in kidney tubule cells is still under investigation Studies so far carried out indicate that it consists of lipid material normally present in myelin but that presumably because of a disorder of the metabolic turnover in myelin lipids it accumulates in abnormal amounts

The form of leukodystrophy with metachromatic breakdown products has been encountered in infants children and young adults and in familial and sporadic cases It has not so far been found in old age The familial diffuse cerebral sclerosis of Scholz has been shown clearly to belong to this group and the similar familial cases of Bielschowsky and Henneberg almost surely do One is therefore justified in classifying this form of the disorder as leukodystrophy of the *Scholz Bielschowsky Henneberg type* or *metachromatic leukodystrophy*

Krabbe Form of Leukodystrophy In this form first described as a familial disorder of infants the lipid breakdown products are also atypical of most pathologic processes which destroy myelin but they differ from those described above in a number of histochemical particulars including absence of metachromasia Typical of this disorder is the occurrence of unusual multinucleated cells with phagocytic properties like foreign body giant cells within which the lipid breakdown products are contained Recent studies have indicated that cerebrosides predominate in the phagocytized lipid This suggests a link with Gaucher's disease although the visceral lesions of the latter condition are absent

More recently cases have been described of a very chronic form occurring in the presenile period in which the atypical lipid products most closely resemble the lipofuscins the "wear and tear" lipid pigment of advancing age

Pelizaeus Merzbacher Form In this form characterized clinically by pronounced familial tendency and very chronic course the myelin lesions tend to be patchy and irregular in contrast with the other forms and there is relative sparing of axones Another distinguishing feature of this condition is that the breakdown products of the myelin although very sparse (as would be expected from the prolonged evolution of the disorder) are of the usual fatty variety rather than the more complex lipids found in the conditions described above

Clinical Aspects The symptoms and signs are those of a progressive dementia often associated in the early stages with weakness and unsteadiness of gait and relatively early signs of corticospinal tract disorder Generalized convulsive seizures may occur but are not invariable No clinical phenomena clearly serve to differentiate leukodystrophy from other diffuse progressive cerebral diseases In the form with metachromatic breakdown products of myelin it is possible to demonstrate metachromatic lipids in the urine which do not occur normally or in other diseases (Austin 1957) In this way the diagnosis can be made during life

Differential Diagnosis Familial occurrence signs referable to a disorder of long projection and association fiber systems and relative lack of convulsive manifestations may suggest the diagnosis during life Otherwise the identification of these conditions requires pathologic examination except in so far as it may be possible to identify the metachromatic

degeneration of the retina (a form of retinitis pigmentosa) Blindness imbecility cerebellar ataxia myoclonic epilepsy and pyramidal tract signs comprise the picture

Adult Form (Kufs, Hallervorden) This is considerably rarer than the childhood varieties The nervous system changes tend to be much less widespread than at earlier ages with corresponding differences in the clinical manifestations and blindness is not nearly so constant a feature Dementia seizures and athetosis have characterized some of the cases The course is much prolonged some patients having lived for 10 or more years after the onset of the illness

In all these diseases, lipids of the class of the gangliosides (Klenk) accumulate in the largest amounts other lipids are less conspicuous Lipoidosis of other organs is slight or absent in this group Of interest is the fact that virtually identical ganglioside accumulation has been demonstrated in the nervous system in gargoylism (lipochondrodystrophy) a rare infantile disorder with bony deformities in which there is abnormality in the formation of connective tissue structures as well (Chap 253)

Niemann Pick Disease This condition in which there is striking enlargement of the liver and spleen because of large amounts of phagocytal lipid in those organs is likewise characterized by extensive lipoidosis of the nervous system which histopathologically appears exactly the same as that in amaurotic family idiocy However in this instance sphingomyelins are greatly increased and the gangliosides only slightly so Similar nervous system lesions have been demonstrated in a few cases of infantile *Gaucher s disease* but not in adult forms The lipid involved appears to be of the class of cerebrosides and the gangliosides were not elevated

PATHOLOGY The characteristic pathologic change is engorgement and distention of nerve cell bodies with the lipids concerned In infantile or childhood cases this is so extensive that all nerve cells in every location including those in peripheral ganglions show this alteration As a rule there is evident breakdown and disappearance of nerve cells and in relation to these destructive phenomena prominent reactive glial changes In infantile cases the lipoidosis of the ganglion cells of the retina imparts to the retina a pale appearance against which the macula stands out sharply as the classic cherry red spot In juvenile cases with atrophy and pigmentary deposits the deeper layers of the retina as well as nerve cells degenerate and the pigment epithelium proliferates

In severe cases the white matter is usually abnormal also This can often be accounted for by the destruction of nerve cell bodies with consequent degeneration of their axonal processes Occasionally however large *regions of white matter are totally* necrotic to a degree that cannot be accounted for by any secondary change This finding suggests a primary disorder of the structure of white matter as well and is reminiscent of the leukodystrophies to be discussed on the following pages

In older individuals the process is less extensive and it can be stated in general that the older the individual or the more chronic the course the less widespread are the neuronal changes No constant localization of the disorder can be pointed out unless it be in the cerebellum which is nearly always affected in the juvenile forms of the disease In some cases the alterations in the basal ganglions have been particularly prominent

No morphologic features serve to distinguish the neuronal alterations in amaurotic family idiocy from those in gargoylism or Niemann Pick disease The latter variety can however be differentiated histochemically

CLINICAL FEATURES In infants and children the combination of rapidly progressive dementia blindness retinal changes and generalized convulsive seizures *often* with widespread *myoclonic* jerks forms a consistent picture As already noted the characteristic appearance of the macula in infantile cases yields place in older children and young adults to optic atrophy possibly with pigment accumulations in the retina Familial occurrence is prominent In the very rare adult cases there is no single characteristic feature Dementia myoclonic jerks and variable degrees of rigidity spasticity weakness ataxia and involuntary movements may be encountered with a slowly progressive course measured in years At the moment no generally useful biochemical *determinations can* be made during life which will assure the diagnosis of a nervous system lipoidosis

DIFFERENTIAL DIAGNOSIS In typical infantile or childhood cases there usually is no difficulty in recognizing this condition In older children and adults the diagnosis may only be suspected after other diffuse disorders—neoplastic infectious nutritional or toxic—have been eliminated by the various currently used diagnostic measures It should always be considered in myoclonic epilepsy with mental deterioration progressive cerebellar ataxia and progressive dementia with seizures and athetosis

Leukodystrophy (Degenerative Diffuse Cerebral Sclerosis)

This rare group of conditions in which familial incidence has frequently been observed is characterized by a diffuse breakdown of white matter in association with a remarkable sparing of the nerve cell bodies in the gray matt

Hepatolenticular Degeneration (Wilson's Disease)

This condition is discussed on pp 725 to 727

CONDITIONS CHIEFLY MANIFESTED BY ABNORMAL POSTURES OR INVOLUNTARY MOVEMENTS

Paralysis Agitans (Parkinson's Disease)

This by no means rare condition was named and classically described by James Parkinson in 1817 His remarkably complete account gives this definition Involuntary tremulous motion with lessened muscular power in parts not in action and even when supported with a propensity to bend the trunk forwards and to pass from a walking to a running pace the senses and intellects being uninjured"

Typically paralysis agitans is a disorder of middle or late life with very gradual progression and a prolonged course Although it has been seen to occur in families (the estimated familial incidence is 6 per cent) it usually is sporadic It bears no consistent relationship to any known disease process such as arteriosclerosis trauma or intoxication although such conditions have often been invoked as etiologically significant and may at times produce somewhat similar clinical manifestations It is well recognized however that the epidemic encephalitis of von Economo which occurred in a world wide distribution in the years following the First World War was followed in a considerable number of cases by a syndrome clinically indistinguishable from paralysis agitans It is usual in such instances to speak of *postencephalitic parkinsonism* whereas the term *Parkinson's disease* should be reserved for true paralysis agitans of unknown cause

Pathology Despite the general familiarity with the condition and an extensive literature on the subject it cannot be said that the pathology of paralysis agitans is yet fully understood The only regularly observed changes have been in the aggregates of melanin containing nerve cells in the brain stem (substantia nigra locus caeruleus dorsal motor nucleus of the vagus) where varying degrees of nerve cell loss with reactive gliosis most pronounced in the substantia nigra along with distinctive eosinophilic intracytoplasmic inclusions (*Lewy bodies* after their description by F H Lewy in 1913) are a consistent finding Changes have also been seen in other structures of the basal ganglions but they are not clearly different in nature or degree from what may be encountered in other patients of similar age without extrapyramidal motor disorders It is tempting therefore to consider paralysis agitans as belonging with the system diseases the affected system being that of the pigmented nuclei of the brain stem It is noteworthy that similar changes in the same groups of melanin-containing cells are likewise found in postencephalitic parkinsonism which pathologically as well as clinically may be extremely difficult to distinguish from paralysis agitans

Clinical Aspects In its fully developed form this disorder cannot be mistaken for any other The stooped posture the stiffness and slowness of movement the rigidity of facial expression and the rhythmic tremor of the limbs which subsides on active willed movement or complete relaxation are familiar to every clinician Although symmetric in the later stages the disorder typically begins asymmetrically e g as a slight tremor of the fingers of one hand or in one leg Also typical is more or less general stiffness of the musculature subserving posture so that even where tremor is inapparent the disease may betray itself by a somewhat staring and immobile facial expression a monotonous voice a general slowness of all motor activity and a curious lack of the little spontaneous movements of postural change that are so characteristic of the normal individual When tremor is minimal patients often are able to alleviate it by resting their hands on a table or the arms of a chair or by keeping them in their pockets The tremor although fluctuating from moment to moment in amplitude and distribution is perfectly regular at a rate of about 4 to 6 per second A fine more rapid tremor may be seen in the early stages of the disease whereas a more violent trembling of greater amplitude characterizes the later course The tremor is generally most pronounced in the hands but may involve also the legs (and thus secondarily the trunk) lips tongue and neck muscles and is easily seen in the eyelids when they are lightly closed There is no total paralysis although general enfeeblement of voluntary movement is characteristic of the fully developed disorder Together with the stooped attitude there is a typical "festinating gait whereby the patient prevented by the abnormality of postural tone from making the appropriate reflex adjustments required for effective walking progresses with quick shuffling steps at an accelerating pace as if to catch up with his center of gravity Clinical examination of the tendon and plantar reflexes discloses no abnormalities There are no sensory changes although deep aching in joints and muscles is common Eventually the patient may become so incapacitated by rigidity and tremor as to be helpless in caring for himself It has often been observed however that even severely disabled patients may under great emotional stress perform complex motor acts quickly and efficiently in a manner that ordinarily would be impossible for them Thus a patient may be able to jump up

variety by appropriate examination of urinary sediment

Progressive Familial Myoclonic Epilepsy

This rare disorder forms a distinct clinicopathologic syndrome characterized by recessive heredity Typically it appears in childhood or early adult life beginning with generalized convulsive seizures which are followed after an interval of years by *myoclonic jerks* of increasing frequency and severity and progressive dementia with death before *middle age* The pathologic features suggest a disorder of nerve cell metabolism the nature of which remains unidentified A link with amaurotic family idiocy is present in a few cases but this does not hold true for all

Pathology In many of the cases on record there are distinctive intracytoplasmic inclusion bodies within nerve cells which may be found at all levels in the central nervous system although they are most frequent in the dentate nucleus of the cerebellum substantia nigra and thalamus These bodies which on the basis of recent histochemical studies react like an acid mucopolysaccharide and which have long been known to have staining properties like amyloid were initially described by Lafora (1911) and are generally known as *Lafora bodies* In addition to these inclusions there is always some degree of nerve cell loss in gray matter structures together with some reactive gliosis In a recently described case with typical clinical findings and pathologically numerous Lafora bodies in brain and spinal cord there was material similar in histochemical reactions to the Lafora bodies contained within heart muscle fibers and liver cells (Harriman and Millar 1956) Some cases have been described with typical clinical features and with degenerative changes in the nervous system similar to those in other cases of this syndrome but with absence of Lafora bodies A few cases are on record in which an indistinguishable clinical picture was associated with the typical pathologic findings of amaurotic family idiocy

Clinical Aspects The onset in most cases is at about the time of puberty or a few years before or after it There is nothing distinctive about the convulsive seizures with which the disorder generally begins The myoclonic jerks are sudden asymmetric or symmetric brief contractions of muscle groups of the limbs face and trunk occurring arrhythmically and unpredictably usually with sufficient force to displace the parts affected They characteristically are provoked by all sorts of stimuli as well as occurring spontaneously and may be so severe as to interfere seriously with willed movements or may cause the patient to fall abruptly The disorder progresses gradually running a course measured in years with terminal stages characterized by profound dementia and total helplessness Treatment with anticonvulsant medication may relieve the generalized convulsive seizures but has no effect on the myoclonic phenomena or the dementia

Hallervorden Spatz Disease

This unusual disorder often familial is associated with a rather variable clinical picture in which the main features are onset in childhood after normal birth and uneventful development abnormalities of posture and muscle tone with involuntary movements and progressive dementia with death in early adult years or before Pathologically characteristic abnormalities in the basal ganglions suggest a metabolic disorder in these regions The classic features of the condition were described in an affected family by Hallervorden and Spatz (1922)

Pathology The distinctive feature of this condition is the accumulation in the globus pallidus and zona reticulata of the substantia nigra of large amounts of pigmented material which imparts a grossly visible brownish discoloration to these regions Microscopically one sees irregular pigmented concretions and granules of varying brownish or greenish hues depending upon the stains used A considerable number of these show the presence of iron and the local tissue iron is increased in amount It is generally believed that these deposits of material consist of substances normally present in the nuclear regions affected but greatly increased in quantity There is no systemic disorder of iron metabolism Destruction of nerve cells is present in these regions and likewise to some extent in the cerebral cortex although it generally is not so severe as in other forms of heredodegenerative brain disease and is overshadowed in severity by the pigmentary disorder in the basal ganglions

Clinical Aspects The disorder typically makes its appearance in childhood or adolescence with abnormalities in muscle tone and movement such as rigidity and choreoathetosis Abnormal postures of the trunk characteristic of torsion spasm (dystonia) may be seen Speech becomes indistinct and there is progressive intellectual impairment Eventually the involuntary movements give way to increasing generalized rigidity and death comes as a rule about 10 years after onset

Differential Diagnosis No feature of the clinical picture serves to distinguish this particular disorder from other conditions showing dementia with extrapyramidal motor abnormalities Hepatolenticular degeneration must be excluded by appropriate laboratory tests The clearly progressive course sets this condition apart from clinically similar abnormalities resulting from accidents or illnesses at birth or in the neonatal period

Hepatolenticular Degeneration (Wilson's Disease)

This condition is discussed on pp 725 to 727

CONDITIONS CHIEFLY MANIFESTED BY ABNORMAL POSTURES OR INVOLUNTARY MOVEMENTS

Paralysis Agitans (Parkinson's Disease)

This by no means rare condition was named and classically described by James Parkinson in 1817 His remarkably complete account gives this definition "Involuntary tremulous motion with lessened muscular power in parts not in action and even when supported with a propensity to bend the trunk forwards and to pass from a walking to a running pace the senses and intellects being uninjured"

Typically paralysis agitans is a disorder of middle or late life with very gradual progression and a prolonged course Although it has been seen to occur in families (the estimated familial incidence is 6 per cent) it usually is sporadic It bears no consistent relationship to any known disease process such as arteriosclerosis trauma or intoxication although such conditions have often been invoked as etiologically significant and may at times produce somewhat similar clinical manifestations It is well recognized however that the epidemic encephalitis of von Economo which occurred in a world wide distribution in the years following the First World War was followed in a considerable number of cases by a syndrome clinically indistinguishable from paralysis agitans It is usual in such instances to speak of *postencephalitic parkinsonism* whereas the term *Parkinson's disease* should be reserved for true paralysis agitans of unknown cause

Pathology Despite the general familiarity with the condition and an extensive literature on the subject it cannot be said that the pathology of paralysis agitans is yet fully understood The only regularly observed changes have been in the aggregates of melanin-containing nerve cells in the brain stem (substantia nigra locus caeruleus dorsal motor nucleus of the vagus) where varying degrees of nerve cell loss with reactive gliosis most pronounced in the substantia nigra along with distinctive eosinophilic intracytoplasmic inclusions (*Lewy bodies* after their description by F H Lewy in 1913) are a consistent finding Changes have also been seen in other structures of the basal ganglions but they are not clearly different in nature or degree from what may be encountered in other patients of similar age without extrapyramidal motor disorders It is tempting therefore to consider paralysis agitans as belonging with the "system diseases the affected "system being that of the pigmented nuclei of the brain stem It is noteworthy that similar changes in the same groups of melanin-containing cells are likewise found in postencephalitic parkinsonism which pathologically as well as clinically may be extremely difficult to distinguish from paralysis agitans

Clinical Aspects In its fully developed form this disorder cannot be mistaken for any other The stooped posture the stiffness and slowness of movement the rigidity of facial expression and the rhythmic tremor of the limbs which subsides on active willed movement or complete relaxation are familiar to every clinician Although symmetric in the later stages the disorder typically begins asymmetrically e g as a slight tremor of the fingers of one hand or in one leg Also typical is more or less general stiffness of the musculature subserving posture so that even where tremor is inapparent the disease may betray itself by a somewhat staring and immobile facial expression a monotonous voice a general slowness of all motor activity and a curious lack of the little spontaneous movements of postural change that are so characteristic of the normal individual When tremor is minimal, patients often are able to alleviate it by resting their hands on a table or the arms of a chair or by keeping them in their pockets The tremor although fluctuating from moment to moment in amplitude and distribution is perfectly regular at a rate of about 4 to 6 per second A fine more rapid tremor may be seen in the early stages of the disease whereas a more violent trembling of greater amplitude characterizes the later course The tremor is generally most pronounced in the hands but may involve also the legs (and thus secondarily the trunk) lips tongue and neck muscles and is easily seen in the eyelids when they are lightly closed There is no total paralysis although general enfeeblement of voluntary movement is characteristic of the fully developed disorder Together with the stooped attitude there is a typical "festinating" gait, whereby the patient prevented by the abnormality of postural tone from making the appropriate reflex adjustments required for effective walking progresses with quick shuffling steps at an accelerating pace as if to catch up with his center of gravity Clinical examination of the tendon and plantar reflexes discloses no abnormalities There are no sensory changes although deep aching in joints and muscles is common Eventually the patient may become so incapacitated by rigidity and tremor as to be helpless in caring for himself It has often been observed however that even severely disabled patients may under great emotional stress perform complex motor acts quickly and efficiently in a manner that ordinarily would be impossible for them Thus a patient may be able to jump up

variety by appropriate examination of urinary sediment

Progressive Familial Myoclonic Epilepsy

This rare disorder forms a distinct clinicopathologic syndrome characterized by recessive heredity Typically it appears in childhood or early adult life beginning with generalized convulsive seizures which are followed after an interval of years by myoclonic jerks of increasing frequency and severity and progressive dementia with death before middle age The pathologic features suggest a disorder of nerve cell metabolism the nature of which remains unidentified A link with amaurotic family idiocy is present in a few cases but this does not hold true for all

Pathology In many of the cases on record there are distinctive intracytoplasmic inclusion bodies within nerve cells which may be found at all levels in the central nervous system although they are most frequent in the dentate nucleus of the cerebellum substantia nigra and thalamus These bodies which on the basis of recent histochemical studies react like an acid mucopolysaccharide and which have long been known to have staining properties like amyloid were initially described by Lafora (1911) and are generally known as *Lafora bodies* In addition to these inclusions there is always some degree of nerve cell loss in gray matter structures together with some reactive gliosis In a recently described case with typical clinical findings and pathologically numerous Lafora bodies in brain and spinal cord there was material similar in histochemical reactions to the Lafora bodies contained within heart muscle fibers and liver cells (Harriman and Millar 1956) Some cases have been described with typical clinical features and with degenerative changes in the nervous system similar to those in other cases of this syndrome but with absence of Lafora bodies A few cases are on record in which an indistinguishable clinical picture was associated with the typical pathologic findings of amaurotic family idiocy

Clinical Aspects The onset in most cases is at about the time of puberty or a few years before or *after it There is nothing distinctive about the con*vulsive seizures with which the disorder generally begins The myoclonic jerks are sudden asymmetric or symmetric brief contractions of muscle groups of the limbs face and trunk occurring arrhythmically and unpredictably usually with sufficient force to displace the parts affected They characteristically are provoked by all sorts of stimuli as well as occurring spontaneously and may be so severe as to interfere seriously with willed movements or may cause the patient to fall abruptly The disorder progresses gradually running a course measured in years with terminal stages characterized by profound dementia and total helplessness Treatment with anticonvulsant medication may relieve the generalized convulsive seizures but has no effect on the myoclonic phenomena or the dementia

Hallervorden Spatz Disease

This unusual disorder often familial is associated with a rather variable clinical picture in which the main features are onset in childhood after normal birth and uneventful development abnormalities of posture and muscle tone with involuntary movements and progressive dementia with death in early adult years or before Pathologically characteristic abnormalities in the basal ganglions suggest a metabolic disorder in these regions The classic features of the condition were described in an affected family by Hallervorden and Spatz (1922)

Pathology The distinctive feature of this condition is the accumulation in the globus pallidus and zona reticulata of the substantia nigra of large amounts of pigmented material which imparts a grossly visible brownish discoloration to these regions Microscopically one sees irregular pigmented concretions and granules of varying brownish or greenish hues depending upon the stains used A considerable number of these show the presence of iron and the local tissue iron is increased in amount It is generally believed that these deposits of material consist of substances normally present in the nuclear regions affected but greatly increased in quantity There is no systemic disorder of iron metabolism Destruction of nerve cells is present in these regions and likewise to some extent in the cerebral cortex although it generally is not so severe as in other forms of heredodegenerative brain disease and is overshadowed in severity by the pigmentary disorder in the basal ganglions

Clinical Aspects The disorder typically makes its appearance in childhood or adolescence with abnormalities in muscle tone and movement such as rigidity and choreoathetosis Abnormal postures of the trunk characteristic of torsion spasm (dystonia) may be seen Speech becomes indistinct and there is progressive intellectual impairment Eventually the involuntary movements give way to increasing generalized rigidity and death comes as a rule about 10 years after onset

Differential Diagnosis No feature of the clinical picture serves to distinguish this particular disorder from other conditions showing dementia with extrapyramidal motor abnormalities Hepatolenticular degeneration must be excluded by appropriate laboratory tests The clearly progressive course sets this condition apart from *clinically similar abnor*malities resulting from accidents or illnesses at birth or in the neonatal period

tense and restless may require judicious use of sedatives

In recent years surgical methods for relief of parkinsonism have received increasing attention and in a few cases the results have been so dramatic and gratifying that this approach to treatment of the disorder cannot be overlooked At present the most effective procedure is the destruction by necrotizing chemical agents or ultra-high frequency electromagnetic vibrations of structures in or near the globus pallidus It seems paradoxical that the effects of a spontaneously destructive lesion of nerve cells in one part of the brain could be overcome in any way by artificially producing additional destructive lesions in another part and yet the practical results show that this is possible No certain knowledge so far exists as to the exact anatomic or physiologic effects of these surgical lesions despite their pragmatic usefulness in selected cases The surgical methods are still in the experimental stage are not without danger and cannot be fully endorsed at this time

Dystonia Musculorum Deformans (Torsion Spasm)

This is a clinical term denoting a state characterized by slow nonrhythmic involuntary movements which produce abnormal at times bizarre postures of the trunk and limbs With passage of time these postures tend to become more or less fixed Underlying the clinical disorder may be any of a number of pathologic conditions such as the residual lesions of epidemic encephalitis the pigmented deposits of Hallervorden Spatz disease (described above) hepatolenticular degeneration (Wilson s disease) or the scars of cerebral birth injury in the broad sense or kernicterus There remain a few rare cases with relatively early onset and progressive course occurring as an hereditary disorder in some instances which justify their consideration as a separate entity

Pathology Very few cases have been studied pathologically In some the caudate nucleus and putamen were the chief sites of disease in others the globus pallidus was affected without significant alteration of other parts of the corpus striatum In addition lesions have been found in the thalamus and subthalamic nucleus in a few instances The abnormalities have consisted of simple cell loss with reactive gliosis without specific features Where torsion spasm has been the major clinical manifestation of one of the diseases mentioned above the distinctive lesions of that particular disorder have been found Whatever their location and nature the pathologic findings are not such that the clinical state could be assumed from their presence alone

Clinical Aspects The motor abnormalities are described in Chap 26 In the early stages the involuntary muscular contractions are intermittent and variable in location and severity but typically interfere with motor performance by superimposing an unwanted posture upon parts in use The term dystonia or torsion spasm is used to refer to these phenomena in the muscles of the trunk and proximal joints of the limbs whereas similar slowly changing abnormal postures of the distal parts of the limbs are generally termed athetosis In cases afflicted with the disorder under discussion both types of abnormality may be present Affection of face and tongue muscles results in faulty articulation of speech which eventually becomes incomprehensible The tendon and plantar reflexes which can be assessed only during moments of relaxation of the affected parts are characteristically normal

Dementia is not a necessary accompaniment of the condition except perhaps in the terminal stages but with severe derangement of all available methods of communication an adequate evaluation of mental capacity may be impossible Typical of most cases has been onset in childhood and slow progression with survival into adult life but not into middle age

Differential Diagnosis Hepatolenticular degeneration should be seriously considered in any case presenting these motor symptoms and appropriate measures should be undertaken for its investigation (see Chap 93) The progressive course and possibly the family history differentiate the degenerative group from the "symptomatic dystonias resulting from infections or metabolic disorders occurring at birth or later

Treatment This is most unsatisfactory Dystonia is notoriously unresponsive to drug therapy although antispasmodic drugs such as those used for parkinsonism should be tried Surgical relief has been attempted in a few cases with some promising early results the ultimate value of this form of treatment has yet to be established

CONDITIONS CHIEFLY MANIFESTED BY ATAXIA

The conditions about to be considered are distinguished clinically by progressive unsteadiness in standing and walking with more or less disturbance of the coordination of other motor acts Pathologically they are characterized by degeneration of the cerebellum and/or its related fiber systems and thus constitute classic examples of the system diseases" Although sporadic instances occur hereditary transmission is an outstanding feature in many cases thus this group of disorders is often referred to as the hereditary ataxias Their subdivision into more or less separate entities is largely arbitrary with pathologic changes of varying distribution underlying clinically indistinguishable symptom complexes Furthermore there is considerable over

and run out of a burning building on hearing the call of Fire! —only to be helpless as before once the crisis is past Although the temporary alleviation under extreme provocation can never be long maintained it is nevertheless true that the general severity of the disorder is considerably influenced by emotional factors being aggravated by anxiety tension and unhappiness and minimal when the patient is in a contented frame of mind Despite the inherently progressive nature of the condition much can be achieved with good medical management and patients may continue for years to live effective happy lives in spite of this affliction Intellectual deterioration is not a consistent feature of paralysis agitans but it must be conceded that in very advanced stages of the condition dementia may be encountered

Differential Diagnosis In typical cases this is not difficult The extrapyramidal syndromes associated with most diseases of known cause or established nature such as cerebral vascular disease cerebral hypoxia (including carbon monoxide asphyxia) or metallic poisoning differ from paralysis agitans in a number of respects such as atypical behavior of tremor presence of signs of pyramidal tract deficit or early onset of dementia etc The differentiation from postencephalitic parkinsonism may be impossible a clear history of an attack of epidemic encephalitis (prolonged somnolence disturbance of consciousness diplopia) and relatively early age of onset of the disorder and the presence of tics localized spasms and oculogyric crises may be the only clues to this diagnosis In recent years a neurologic disorder strikingly similar to Parkinson's disease has been seen following the prolonged administration of large amounts of reserpine and similar drugs which subsides on withdrawal of the offending drug—a matter of considerable theoretic and practical importance Parkinsonism is probably never produced by cerebral neoplasm

Treatment Although as with the other degenerative nervous diseases no known treatment influences the underlying disease process patients with paralysis agitans can often be greatly helped by well managed symptomatic therapy As already suggested an important part of any such program is to help the patient by means of sympathetic understanding to comprehend the nature of his illness to accept his fate and to carry on courageously in spite of it The constant tremor and rigidity result in physical fatigue thus patients generally require more rest than previously Physical measures such as cool clothing massage and stretching exercises may promote greater muscular relaxation and alleviate the muscle and joint aching which may be prominent and early symptoms of the disease

Along with these general supportive measures optimum treatment in most cases requires the wise use of antispasmodic drugs singly or in combination The program of medication in each case must be on an individual basis with choice of drugs and adjustment of dosages under close medical supervision until a maximum of therapeutic benefit with a minimum of toxic side effects is achieved At best only a partial relief of symptoms can be expected, with rigidity in general responding better than tremor although even the latter may be considerably allayed in some cases but even partial relief may make the difference between effective living and incapacity

The drug treatment of paralysis agitans (and postencephalitic parkinsonism) is on a purely empirical basis It has long been known that some relief can be obtained with drugs of the belladonna group (atropine scopolamine stramonium) and these substances are still extensively used A number of synthetic antispasmodics have become available and appear to be more effective in many instances than the older forms of medication Preparations of this kind are trihexyphenidyl (Artane) ethopropazine hydrochloride (Parsidol Lysivane) procyclidine hydrochloride (Kemadrin) cycrimine hydrochloride (Pagitane) benzatropine methane sulfonate (Cogentin) and caramiphen hydrochloride (Panparnit) Some of the antihistamines such as phenindamine (Thephorin) and diphenhydramine (Benadryl) have likewise been shown to be helpful A combination of drugs is often better than one alone A recommended program is to begin with Parsidol 10 to 20 mg three to four times daily and to increase this gradually at 3 day intervals to a maximum of one 100 mg tablet four times daily If the patient already is taking one form of medication for this condition and it is desired to substitute another form the older medication must be discontinued gradually by small decrements rather than abruptly while the newer one is being increased to full dosage otherwise a severe increase of rigidity or tremor may occur Toxic effects include nausea lightheadedness drowsiness and particularly in older patients mental confusion often at night These effects subside rapidly when smaller dosage is resumed Once the optimum dosage with this preparation is reached further therapeutic benefit may be achieved by adding other drugs such as Artane (2 mg or 5 mg tablets three to four times daily) or Thephorin (25 to 50 mg three to four times daily) or both It is to be emphasized that any of these drugs should be given to the threshold of toxicity before being discontinued as ineffective and that dryness of the mouth is an unavoidable side effect Occasional patients with drowsiness or sluggishness are helped by the additional use of analeptics (dextroamphetamine 5 mg two to three times daily) but not late in the day so that sleep is not disturbed Patients who are

a distinct entity Marie tried to point out, on the basis of a number of case reports in the literature of the time *that there were other cases of hereditary ataxia* of later onset which could not be fitted into Friedreich s description *He offered the suggestion* that the cerebellum itself was the major site of disease in these cases *Subsequent pathologic examination* of the cases he reviewed have shown that he was partly in error in this supposition nevertheless following his report the concept of Marie s ataxia has become firmly established in the writings on hereditary ataxia Thus on the basis of tradition and clinical convenience it is retained here

Pathology As indicated above and as with the late life ataxias there is no one characteristic pathologic change in this group of cases even *though the clinical disorder is identical* Some patients have had degenerative changes in the spinal cord indistinguishable from those of Friedreich s ataxia Others have shown cerebello-olivary degeneration or olivopontocerebellar atrophy

Clinical Aspects The principal basis for separating out this group of cases is their onset in early adult life and their hereditary nature The signs of an associated chronic peripheral neuropathy so distinct a feature of Friedreich s ataxia are not prominent in this group In general the clinical features are those already described above Signs of pyramidal tract deficit are variably present and dementia occurs in some cases A relatively long course can be expected (about a decade or possibly two) although death from intercurrent disease comes earlier than would be expected for the ordinary healthy individual

Friedreich s Ataxia

This classic form of hereditary ataxia, first clearly depicted by Nikolaus Friedreich of Heidelberg in 1863 forms a relatively distinct symptom complex which generally runs true to form although it overlaps other heredodegenerative syndromes particularly chronic peripheral neuropathies and progressive optic atrophy conditions to be discussed subsequently Friedreich s ataxia is typically a disease of childhood or adolescence although onset at a somewhat later age has occasionally been seen In some families the disorder occurs with dominant inheritance it is a recessive trait in others

Pathology The outstanding abnormalities are in the spinal cord and peripheral nerves and are typical of a chronic degenerative process In the cord the principal changes are in the sensory fibers of the posterior columns in the spinocerebellar tracts and in the lateral corticospinal (pyramidal) tracts Additional lesions of varying extent may be found in the brain stem and in the cerebellum itself although the latter structure is often intact Involvement of other parts of the central nervous system at even higher levels occasionally occurs In the *peripheral nerves the lesions vary likewise in severity* and extent They resemble those encountered *in the chronic peripheral neuropathies described* below Thus even so relatively discrete an entity *as the Friedreich form of hereditary ataxia is neuro*pathologically far from homogeneous In some cases there is a peculiar form of myocardial degeneration resulting in thickening and fibrosis of the myocardium No other visceral lesions are regularly encountered

Clinical Aspects As with other progressive ataxias the disorder first appears in the legs Thus the child patient previously healthy begins to stagger and lurch in walking and is unsteady often in a tremulous fashion on standing Clumsiness and *intention tremor of the hands and arms appear later* along with faulty articulation and abnormal rhythm (scanning) of speech The limbs in addition to being ataxic generally show considerable weakness Examination usually discloses nystagmus and skeletal deformities—kyphoscoliosis the basis for which is not certain and a peculiar foreshortening and high arching of the feet (pes cavus) with cocking up of the toes sometimes called the *Friedreich foot* Typically there is the unusual combination of total absence of deep (tendon) reflexes with extensor plantar reflexes (Babinski sign) Position and vibration senses in the legs are usually impaired and often in the hands as well In some patients impairment of cutaneous sensation (pain and temperature light touch) is demonstrable in a roughly stocking and glove distribution The optic disks may be pale indicating optic atrophy although actual blindness is relatively rare Some patients are of low intelligence or may become demented in the course of the disease Survival beyond early adult life is rare with death frequently the result of associated myocardial disease

Occasionally very mild or fragmentary forms of the disorder (such as pes cavus and absent or hyperactive tendon reflexes) may be encountered with little if any disability or progression Such abnormalities are most likely to be seen in other members of the family of a patient afflicted with the fully developed form

Differential Diagnosis The classic form of Friedreich s ataxia is readily recognizable and cannot easily be confused with other conditions It is to be expected however that variations in the clinical manifestations may occur because of the variable pathologic changes One particularly well known variant was described in 1926 by Levy and Roussy in which the muscle wasting of the legs is severe and is combined with areflexia and a sensory ataxia There have been reports of Friedreich s ataxia in some members of a family and of the Levy Roussy

lapping with other forms of hereditary nervous disease so that in a given case a remarkable combination of defects may be encountered These facts have led to the idea that in this group there is a set of closely related genetically determined abnormalities which may occur together in an almost infinite series of combinations so that it is not possible to separate out well defined disease pictures Nevertheless certain constellations of symptoms and pathologic findings occur with sufficient regularity to warrant their separation for purposes of discussion The classification about to be given is not entirely satisfactory but is designed to be of practical help to the physician confronted with a case

Cerebellar Degenerations of Late Life

These disorders present themselves clinically as progressive ataxia beginning in middle age or later Most sporadic cases come into this group but there are some cases of hereditary ataxia as well which do not make their appearance until the later years of life The rare form of spinocerebellar degeneration associated with the presence of carcinoma *subacute carcinogenic spinocerebellar degeneration* can also be considered here although its relationship to the spontaneously occurring forms is not at all clear

Pathology There is grossly visible atrophy of the cerebellum which may be most striking in the superior aspect of that organ or in the midline (vermis) but may affect the entire cerebellum Microscopically there is widespread loss of nerve cells in the cerebellar cortex chiefly affecting the Purkinje cells but often involving the granule cells as well When the abnormalities are so confined it is usual to speak of *cortical cerebellar atrophy* Closely related and perhaps basically identical is *cerebello olivary degeneration* where in addition to atrophy of the cerebellar cortex there is nerve cell loss in related parts of the inferior olivary nuclei of the medulla oblongata generally interpreted as transsynaptic degeneration secondary to the disease process in the cerebellar cortex In another striking group of cases there is in addition severe degeneration of the pontine nuclei and middle cerebellar peduncles this is called *olivopontocerebellar degeneration* In such cases there may be degenerative changes in other neuronal systems particularly the cerebral cortex and basal ganglions More rarely in the late life group disease may be found in the spinal cord affecting posterior columns spinocerebellar tracts and corticospinal tracts in varying combinations such lesions are more characteristic of the hereditary group or the form associated with carcinoma than of sporadic cases

Clinical Aspects The disorder almost always makes its appearance first in the legs resulting in unsteadiness of stance and gait of the peculiar wavering lurching character so typical of cerebellar ataxia (see Chap 26) Disturbance in articulation and rhythm of speech occurs early in the disease and may progress to total incomprehensibility After the lapse of years the arms likewise become ataxic although in older individuals death may supervene before this stage is reached Nystagmus may occur but it is often absent In some cases there is exaggeration of deep reflexes with extensor plantar responses and in a few (e g with olivopontocerebellar atrophy) there may be rigidity and Parkinson like tremor in addition to the ataxia A number of patients have shown progressive dementia so that it is proper to speak of such patients as having a cerebrocerebellar degeneration Progression is very gradual and slow being measured in decades and may not necessarily shorten life In the cases associated with carcinoma the tempo of evolution of the process is much more rapid with severe disability coming on within a period of months There is no response to any known form of treatment in any of the progressive ataxias although encouragement and gait training may enable a patient to overcome his disability to some extent

Differential Diagnosis The slow but relentless progression in the absence of increased pressure or signs of inflammation in the cerebrospinal fluid serve to distinguish this degenerative group from other forms of cerebellar ataxia such as may occur with neoplastic infectious or demyelinative disease drug intoxications (e g barbiturates) or heat stroke (onset of cerebellar ataxia during periods when temperature is 106 F or over) The degenerative disorders under discussion tend to occur in a setting of otherwise good general health this together with other clinical differences distinguish them from the ataxia of deficiency disease such as the Wernicke Korsakoff syndrome (see Chap 258) The carcinogenic form of spinocerebellar degeneration may be distinguished from direct carcinomatous involvement of the nervous system by the symmetry of the findings and the absence of increased intracranial pressure The alcoholic cerebellar degeneration usually develops rapidly and then remains more or less stationary for the remainder of the patient s life (cf Chap 258)

Hereditary Ataxia of Pierre Marie

Included here are cases of hereditary progressive ataxia with onset in early adulthood which conform neither to the typical syndrome of Friedreich s ataxia (to be described below) nor to the late life ataxias just discussed Considerable doubt has been raised as to the validity of retaining the concept of Marie s hereditary ataxia because pathologically this is by no means a uniform group When Pierre Marie wrote about the subject in 1893 Friedreich s ataxia had relatively recently become recognized as

erally suffices in such instances to exclude serious neurologic disease

Progressive weakness from intrinsic disease of muscle (myopathy polymyositis) may occasionally be difficult to distinguish from progressive muscular atrophy of the type under discussion yet the differentiation is important from the standpoint of prognosis or treatment Under such circumstances the diagnosis can be made by muscle biopsy and electromyography

Infantile Muscular Atrophy (Werdnig Hoffmann) Amyotonia Congenita (Oppenheim)

The form of progressive muscular atrophy described by Werdnig and Hoffmann is a disease of infants and young children typically afflicting several members of a family Pathologically it closely resembles the adult disease described above *Amyotonia congenita* is a purely clinical term used to designate abnormal laxness of somatic musculature observed at birth or in early infancy it may occur in a number of different pathologic processes including the Werdnig Hoffmann disease For further details of these conditions Chap 253 should be consulted

Hereditary Spastic Paraplegia

This very rare disorder is characterized by early onset (childhood or adolescence) and slow progression of weakness and spasticity of the legs Later the arms may be affected usually to a lesser degree The pathologic changes closely resemble those of Friedreich s ataxia and there is reason now to believe that this condition is in fact an incomplete form of Friedreich s disease in which spastic weakness overshadows minimal or absent ataxia and sensory changes The diagnosis is made by the family history and by excluding other possible causes of bilateral spastic weakness of the limbs The relationship to Friedreich s ataxia is further confirmed by the occurrence in some cases of pes cavus and optic atrophy One group of these patients also suffers a progressive dementia

CONDITIONS COMBINING MUSCULAR WEAKNESS AND WASTING WITH SENSORY CHANGES

Syringomyelia and Syringobulbia

Among neurologic diseases this condition characterized by cavity formation in the spinal cord or medulla is not at all rare There is no universal agreement as to its nature although in general it is considered to belong in the class of developmental disorders or embryologic malformations Yet the usual onset of disability in adult life (before middle age) and its progressive course as well as its unknown cause are features it shares in common with many of the degenerative diseases Familial syringomyelia has been reported but is extremely rare the cases generally seen are sporadic

Pathology The cavity (Greek *syrinx* "pipe" or "tube) is most frequently located in the cervical enlargement of the spinal cord Typically it is independent of the central canal of the cord but lies dorsal to it and extends laterally and posteriorly into one or both posterior horns of gray matter and sometimes anteriorly into the ventral horn it also has a long vertical extent through many segments of the cord Usually the cavity is lined with sparsely cellular astrocytic glial tissue but when it communicates with the central canal (as it does in some cases) it may be lined in places with ependymal cells The cavity is virtually always in a position to interrupt the crossing fibers carrying pain and temperature sensations and if it is sufficiently large it involves as well the anterior horns and lateral corticospinal tracts In far advanced cases the cord is reduced to a thin hollow shell distended with cerebrospinal fluid under such circumstances the cord may rarely occupy the entire space in the vertebral canal producing spinal subarachnoid block Syrinx formation occurs much less frequently in the lumbosacral cord where it has the same characteristics as in the cervical region In occasional cases cavitation may extend all the way up and down the cord The cavity has a very typical location in the medulla seen in cross section it forms an oblique slit extending from the floor of the fourth ventricle between the hypoglossal nucleus and dorsal motor nucleus of the vagus to the periphery immediately dorsal to the inferior olive This results in significant clinical effects discussed below Although typical syringomyelia may be found in association with tumors within the spinal cord such as intramedullary glioma or hemangioblastoma the condition does not necessarily depend on the presence of neoplasms Frequently there are other defects or malformations in other organs such as abnormalities of the skull or cervical spine or spina bifida but these are not constant, although kyphoscoliosis to which reference is made below is regularly found

Clinical Aspects The symptoms and signs are referable to an asymmetric but centrally placed lesion in the spinal cord (cf Chap 27) Because of the effect on sensory pathways sensory abnormalities are nearly always found At first there is loss of pain and temperature sensation alone—a defect of which the patient may not be aware—which extends most typically over the shoulders arms and hands in a capelike distribution As the cavity enlarges other forms of sensation may be lost but still in a segmental distribution with intact sensa

syndrome in others In the absence of family history and with atypical clinical findings further diagnostic studies to exclude tumor infections intoxication or congenital malformation will be necessary

CONDITIONS WITH OUTSTANDING MUSCULAR WEAKNESS AND WASTING, WITHOUT SENSORY CHANGES

Motor System Disease

This general term is used to indicate a progressive disorder of motor neurones in cerebral cortex brain stem and spinal cord manifested clinically by muscular weakness with muscle atrophy and spasticity with exaggeration of deep reflexes in varying combination It is a disease of middle life generally appearing in the fifth or sixth decades Customarily a subdivision is made on the basis of the particular grouping of symptoms and signs observed Thus the most frequent form in which muscular atrophy and hyperreflexia are combined is called *amyotrophic lateral sclerosis* Rather more rare are the cases in which weakness and atrophy alone exist without clinical evidence of corticospinal tract dysfunction for these the term *progressive muscular atrophy* is used Where the disorder affects predominantly the musculature innervated by the cranial nerves it is usual to speak of *progressive bulbar palsy* Very rarely the picture is dominated by spasticity and hyperreflexia without obvious muscular wasting such cases are classed as *primary lateral sclerosis* There is no reason to believe that these subgroupings are anything other than clinical variants of the same disease process which is another classic example of a "system disease Most cases are seen as sporadic instances and an hereditary basis was long denied by competent observers Yet there is recent evidence that the disease can occur in its classic form as an inherited disorder not infrequently as a mendelian dominant (Kurland et al 1955)

Pathology There is widespread selective atrophy and loss of motor nerve cells at all levels of the central nervous system Some evidence of disease in the corticospinal motor system is usually found pathologically even when physical signs referable to such changes were not observed during life The spinal cord typically shows some loss of nerve fibers in the lateral and anterior columns in addition to the obvious corticospinal tract degeneration although no clinical changes can generally be related to such lesions The atrophy of fibers in skeletal muscles is typically that due to loss of motor innervation

Clinical Aspects The disease begins insidiously and may be well advanced before the patient is aware of it Although often asymmetric initially the weakness and muscular wasting gradually become symmetric and widespread Classically the disorder becomes first evident in the small muscles of the hands but it may begin in one or both legs or in muscles supplied by cranial nerves Vague feelings of discomfort in the muscles tightness numbness (without objective sensory changes) and recurrent cramps may be early symptoms The progressive atrophy of the musculature is accompanied by widespread visible fascicular twitchings of groups of muscle fibers a classic feature Despite extensive involvement of skeletal muscles generally sphincter control remains intact Sooner or later the disease affects muscles supplied by the brain stem resulting in weakness atrophy and fasciculations in the tongue and facial musculature dysarthria and impairment of chewing or swallowing The functions of the ocular muscles oddly enough are invariably spared Affection of corticobulbar fibers results in such manifestations of pseudobulbar palsy as involuntary weeping or laughter exaggerated reflex movements of the facial muscles of expression and sucking reflexes Progression is unhalting and relatively rapid leading to extensive paralysis with death from respiratory weakness or aspiration pneumonia generally within about 2 years from onset Intelligence and awareness are typically preserved to the end

Differential Diagnosis Other forms of spinal cord disease neoplastic inflammatory or mechanical for which effective treatment is available may at times resemble amyotrophic lateral sclerosis particularly where involvement of the cervical cord (e g spondylosis with osteophytic overgrowth in the cervical spinal canal) produces weakness wasting and fasciculations in the upper limbs and spasticity in the legs The absence of cranial nerve involvement may be helpful in differentiating such cases although some compressive lesions at the foramen magnum may implicate the twelfth cranial (hypoglossal) nerve with resulting affection of the tongue Absence of pain or of sensory changes normal function of bowels and bladder normal roentgenographic studies of the spine and absence of changes in the composition or dynamics of the cerebrospinal fluid are all points in favor of degenerative disease and against other conditions but where doubt exists contrast myelography should be performed Nutritional myelopathy can be excluded by history and on other clinical grounds

Although fasciculations are a prominent feature of motor system disease they are not in the absence of weakness muscle atrophy or loss of tendon reflexes valid signs of it for they may occur in a variety of metabolic or toxic disorders (e g thyrotoxicosis salt depletion) as well as in otherwise healthy individuals Careful clinical evaluation gen

described by Refsum (1946) and called by him *heredopathia atactica polyneuritiformis* in which peripheral neuropathy and ataxia are associated with progressive nerve deafness retinitis pigmentosa and a high cerebrospinal fluid protein Although the pathologic background of this particular variety is yet to be fully investigated some of the findings suggest changes in the central nervous system resembling those of amaurotic family idiocy (neuronal lipoidosis) in addition to lesions much like those in Friedreich's ataxia

Pathology The lesions are typical of a chronic multiple peripheral neuropathy with secondary atrophic changes in muscles The atrophic process in the nerve fibers is associated with some abortive regenerative phenomena and with proliferation of connective tissue and Schwann cells which in the hypertrophic variety may reach extreme degrees In such cases and also in some others where the nerve trunks were not enlarged the spaces between the remaining fibers are filled with a peculiar loose textured connective tissue in the interstices of which there is a mucinous fluid—a characteristic but still unexplained abnormality In the central nervous system there are varying degrees of overlap with the lesions found in the various forms of hereditary ataxia already discussed

Clinical Aspects The disorder usually begins in childhood and progresses very slowly In the classic cases of peroneal muscular atrophy the combination of pes cavus with extreme atrophy of the anterior tibial and calf muscles (stork legs) and wasting of the lower thigh musculature (giving an appearance like an inverted champagne bottle) presents a striking picture There is total absence of deep reflexes and sensation is altered as described above under Friedreich's Ataxia The possibility of combinations with other hereditary neurologic syndromes has already been pointed out Although death in a state of extreme debility in early adult life is common progression in some cases may be extremely slow and may lead to very little disability

Differential Diagnosis It may be necessary to exclude chronic intoxications that produce polyneuropathy (lead arsenic chronic medication with isonicotinic acid hydrazide) or nutritional neuropathy or multiple neuropathy with malignant neoplasms (bronchogenic carcinoma multiple myeloma) or amyloid neuropathy but in general these conditions are sufficiently unlike the heredodegenerative forms to prevent confusion with them Apart from the family history the early onset and slow progression in the face of good general health the absence of significant cerebrospinal fluid changes and generally distinctive pattern of involvement are sufficient for the accurate recognition of the degenerative neuropathies In occasional sporadic or atypical cases biopsy of muscle and of a small cutaneous nerve twig (most conveniently the sural cutaneous nerve) will be necessary

Treatment Although no specific treatment is available patients whose disease is of slow progression and in whom conditions are otherwise favorable may be greatly helped by measures to ensure a stable walking surface such as corrective shoes braces to prevent foot drop and even orthopedic procedures to stabilize the joints

CONDITIONS CHIEFLY MANIFESTED BY VISUAL LOSS

As already stated in previous sections progressive impairment or loss of vision due to degenerative changes in the visual system (retinas and optic nerves) may be an accompaniment of morbid processes affecting the nervous system diffusely—in particular the nervous system lipoidoses and the large group of the hereditary ataxias Occasionally however the peripheral visual system is the major or only site of disease In such cases the disorders are strongly hereditary For detailed discussion of these conditions standard reference works on ophthalmology should be consulted Nevertheless two entities because of their close relationship with other degenerative diseases of the nervous system warrant some discussion here

Hereditary Optic Atrophy (Leber)

This rare condition is characterized by the relatively rapid development of bilateral blindness with optic atrophy coming on in early adult life It was first thoroughly described by Leber in 1871 Typically it occurs as a sex linked recessive trait chiefly affecting men but it likewise may be seen in women

Pathology In the only recorded case with autopsy the changes occurred primarily in the ganglion cells of the retina with secondary degeneration in optic nerve fibers Because of the limited examination in this case it is not known whether there were lesions in other parts of the nervous system

Clinical Aspects The condition often begins asymmetrically with blurring of vision in one eye followed in days or weeks by similar affection of the other eye Vision then deteriorates rapidly over ensuing weeks or months generally with eventual total blindness as a result although arrest before this stage has been seen or even a little improvement after initial steady progression In the early stages examination of the visual fields shows large central scotomas The optic disks may be normal at first or may be swollen (optic neuritis) later the appearance is typically that of optic atrophy with pale clearly outlined disks

tion in the lower parts of the body As a rule one finds weakness wasting loss of tendon reflexes and fasciculations in the muscles of the hands and arms and spastic weakness with signs of pyramidal tract deficit in the legs If the syrinx extends into the preganglionic center for sympathetic innervation of the pupil in the lateral horn of gray matter at the eighth cervical to first thoracic levels this results in Horner's syndrome on the affected side The typical cleft in syringobulbia is so placed as to interfere with connections between the vestibular nuclei and medial longitudinal fasciculus and between the descending nucleus and tract of the trigeminal nerve and the trigeminothalamic pathways thus nystagmus and sensory impairment on the face (with loss of the corneal reflex) generally result The lesion also may involve the hypoglossal fibers and the nucleus ambiguus of the vagus thereby giving rise to atrophy of one side of the tongue and unilateral palatal and vocal cord paralysis Kyphoscoliosis is an almost universal feature of syringomyelia The mechanism appears to be an unequal atrophic paralysis of paravertebral muscles It may precede the other neurologic abnormalities by many years The impaired sensation and interference with autonomic innervation frequently are associated with trophic changes in the affected segments—such as edema and cyanosis of the hands ulcerations of the skin and painless destruction of joints reproducing the Charcot joints of tabes dorsalis Occasionally the disease appears in childhood but usually the clinical manifestations do not become apparent until young adult life It is slowly progressive but not always steadily so and there may be long periods of arrest or even slight remission

Differential Diagnosis This is not difficult in typical and well advanced cases but the possibility of spinal cord tumor must always be kept in mind when the syringomyelic syndrome is encountered and steps must be taken to rule it out Other compressive lesions inflammatory or traumatic likewise must be excluded The suspicion of syringomyelia may at times be strengthened by the roentgenographic finding of widening of the interpedicular spaces of the cervical vertebrae but this merely indicates the presence of a chronic enlargement of the cord and does not disclose its nature Multiple sclerosis may at times produce similar sensory changes but almost never causes weakness of lower motor neurone type Conversely motor system disease which can produce motor abnormalities resembling those of syringomyelia never results in detectable sensory changes

Treatment On the theory that the cavitation may result from an intrinsic and independent proliferation of the glia (with breakdown in the center of the gliosis to form the syrinx) x ray therapy has been used for many years in attempts to treat syringomyelia Although some patients appear to benefit from this the results are generally disappointing Nevertheless radiation in small amounts under the guidance of an expert roentgenologist, may be warranted in selected cases In those cases in which the syrinx becomes distended with fluid in subarachnoid block, laminectomy and drainage of the cavity may produce considerable benefit On the whole however there is no satisfactory form of treatment for these cases

Progressive Neural Muscular Atrophy

The remaining group of degenerative disorders characterized by progressive weakness and wasting of skeletal muscles combined with sensory changes are chronic diseases of peripheral nerves often occurring as hereditary conditions Although clinical and pathologic subvarieties exist there is no sharp dividing line between them and they are best considered together under the designation given above in which the term *neural* emphasizes the peripheral nerve affection As already pointed out above chronic peripheral neuropathy is an associated disorder in some of the hereditary ataxias and is regularly encountered in the classic form of Friedreich's ataxia An additional connecting link with other genetically determined nervous diseases is the occurrence of progressive optic atrophy or pigmentary degeneration of the retina in some cases Common to all is for the neuropathy to begin distally and to progress in a centripetal fashion and for the feet and legs to become first affected with involvement of the hands and more proximal parts only after a considerable interval

The variety most usually seen is that generally called *peroneal muscular atrophy* (Charcot Marie Tooth disease) which draws attention to the changes in the lower legs although the disorder affects far more than the peroneal muscle groups or nerves Although it had been previously described it was first clearly differentiated from other forms of muscular atrophy by Charcot and Marie in France and independently by H H Tooth in England in 1886 In rare cases which are otherwise similar there is a remarkable palpable thickening of peripheral nerve trunks Such cases are generally designated *hypertrophic interstitial neuropathy* (of Dejerine and Sottas after the French neurologists who in 1893 first described the condition clinically and pathologically) In a few cases there are pronounced trophic and vasomotor abnormalities of the affected parts chiefly the feet which may lead to chronic poorly healing perforating ulcers on the ball of the foot among other abnormalities (*familial neurovascular dystrophy* Wadulla 1949 Krucke 1955 *hereditary sensory neuropathy* Denny Brown 1951) Probably related is the unusual condition

260 DISEASES OF THE PERIPHERAL NERVES

Vincent Perlo and Raymond D Adams

Definition According to common clinical usage multiple symmetric involvement of peripheral nerves resulting in varying degrees of muscular weakness and sensory impairment is termed *polyneuritis* *Mononeuritis* indicates involvement of single nerves *Neuritis* implies inflammatory disease of nerves but inflammatory reactions in the neuritides are uncommon compared with the incidence of toxic metabolic or ischemic processes The terms *neuropathy polyneuropathy* and *mononeuropathy* are considered preferable in describing noninflammatory conditions

General Considerations The peripheral nervous system includes 12 pairs of cranial nerves originating from the brain and 31 pairs of segmentally arranged spinal nerves arising from the spinal cord The parts of the spinal nerves within the spinal canal and attached to the ventral and dorsal surfaces of the cord are called *roots* The dorsal roots contain afferent fibers of which the cells of origin are in the dorsal root ganglions while ventral root fibers arise from anterior horn cells in the gray matter of the cord The dorsal and ventral roots join to form the spinal nerves just outside the intervertebral foramens Each spinal nerve receives fibers from the sympathetic trunk of its own side

The peripheral nerves are composed of myelinated and unmyelinated nerve fibers bound together by endoneural connective tissue Each fiber bundle is surrounded by a connective tissue sheath or perineurium and groups of bundles are enveloped by epineurium forming nerve trunks The nerve fibers or axones vary in size and in the number of myelinated fibers The myelinated fibers are surrounded by a sheath of myelin and this in turn is invested by a thin membranous neurilemma sheath The myelin sheaths are interrupted by nodes of Ranvier and each segment of myelin contains a single Schwann cell Motor fibers are generally large and myelinated while sensory branches are composed mainly of smaller myelinated and unmyelinated fibers Each nerve has its own vascular lymphatic and nerve supply Affection of single or multiple nerves or roots results in varying degrees of sensory loss motor weakness and autonomic disturbance depending on the severity of the lesion and the type of fibers involved

Pathologically the different diseases of the peripheral nerves have certain points in common Degeneration of medullated nerve fibers is found in all though it varies in degree and site of the primary damage The myelin sheaths are most susceptible The sheath disintegrates and forms ovoid masses or balls and often fine droplets These excite a reaction in the histiocytes which are converted into fatty macrophages as they phagocytize particles of myelin This myelin change may be limited to a few segments of the myelinated fiber a condition sometimes referred to as the *periaxial degeneration of Gombault* or the entire nerve distal to the point of damage may be affected (so-called *Wallerian degeneration*) The axis cylinders may swell, become granular and undergo fragmentation But as a rule axis cylinder damage is less pronounced than that of the myelin sheath

The location of the primary damage varies In acute idiopathic and diphtheritic polyneuritis the dorsal and ventral roots spinal ganglions and spinal nerves bear the brunt of the damage and the more peripheral parts of the nerve are affected only very slightly if at all In diabetic polyneuropathy ganglions root and proximal nerves are involved and this may extend secondarily to the spinal cord In alcoholic and arsenical polyneuropathy and many cases of porphyria the changes are mostly in the peripheral segments of the nerves Very commonly the axis cylinders are affected relatively little in comparison with the myelin sheaths The degeneration of dorsal root ganglion cells occurs in only a few types of polyneuritis such as diabetic idiopathic and diphtheritic polyneuritis When the ganglion cell is destroyed there is invariably a degeneration of the axis cylinder and myelin sheath in the peripheral nerve dorsal root and posterior columns of the spinal cord Whenever the motor nerve fibers degenerate the anterior horn cells within the spinal cord swell and undergo chromatolysis (axonal reaction)

The various types of polyneuritis are distinguished then by the character and extent of the nerve fiber changes However certain other pathologic changes also serve to differentiate them In idiopathic polyneuritis there is an infiltration of inflammatory cells i e lymphocytes plasma cells and mononuclears in the roots spinal ganglions and nerves In polyarteritis nodosa not only is the nerve degeneration distributed in foci according to the location of vascular occlusion but there is a unique necrotizing panarteritis Amyloid neuritis is identified by the deposits of material staining like amyloid in the intraneural blood vessels and connective tissue

The pathogenesis of diseases of the peripheral

Differential Diagnosis Multiple sclerosis may at times act in a manner identical to that just described but without a definite hereditary background and with a much better outlook for improvement of vision Toxic or nutritional amblyopia can generally be excluded by history and associated clinical findings In some cases it may be necessary to eliminate the possibility of a tumor compressing the chiasmal region and optic nerves although some evidence of bitemporal field defects would be then expected rather than bilateral central scotomas alone In addition to careful roentgenograms of the skull and cerebrospinal fluid examination pneumoencephalographic visualization of the chiasmal region may be indicated in case of serious doubt

Pigmentary Degeneration of the Retina (Retinitis Pigmentosa)

This may at times occur as a relatively independent disorder although it is often associated with other abnormalities of which cataracts deafness and mental deficiency are outstanding It is strongly hereditary chiefly as a recessive trait although dominant inheritance has been seen Pigmentary degeneration of the retina is one of the features of the Laurence Moon Biedl syndrome (Chap 28) It also accompanies some cases of neuronal lipoidosis or hereditary ataxia as already noted

Pathology The principal lesion is a degeneration of the rods and cones associated with displacement of melanin containing cells from the pigment epithelium into more superficial parts of the retina Other retinal structures are relatively intact

Clinical Aspects The disorder typically begins in childhood first as night blindness The visual fields become concentrically narrowed from the periphery to the center until eventually (by adolescence or perhaps not until middle age) very little useful vision remains Ophthalmoscopic examination may be normal at first but generally discloses irregular patches of dark pigment in the periphery of the retina When cataracts are likewise present as sometimes is the case visual acuity may be significantly improved by their removal The frequent association of the retinal lesions with other abnormalities has been mentioned in previous paragraphs

Differential Diagnosis Chorioretinitis from other causes (e g syphilis) may present a similar ophthalmoscopic appearance and should be excluded The hereditary background and the progressive course with night blindness and peripheral constriction of the visual fields may lead to the diagnosis even in the rare cases where pigmentary deposits in the retina are absent In most instances the opinion of a qualified ophthalmologist must be obtained

CONCLUSION

An attempt has been made to summarize information about some of the most important of the large group of the degenerative diseases of the nervous system Although there have of necessity been some omissions it is hoped that this chapter may serve as a guide to what may seem to be an impenetrable maze of eponyms and overlapping syndromes

Paralysis of the external ocular muscles may occur in exceptional cases

The tendon reflexes are occasionally retained in the early stages of polyneuropathy but by the time sensory and motor paralysis has developed they are nearly always lost Reflex loss may be restricted to the legs—absent knee and ankle jerks —or there may be generalized areflexia Cutaneous reflexes i e abdominal and plantar are not affected

In certain cases vasomotor changes in the skin occur These include excessive sweating mottling cyanosis and edema Vasomotor paralysis resulting in hot dry skin is less frequently observed In chronic forms of polyneuropathy postural syncope may occur as a consequence of this vasomotor paralysis

CLINICAL VARIETIES OF POLYNEUROPATHY

Acute Polyneuritis

Acute Idiopathic Polyneuritis Acute idiopathic polyneuritis (infectious polyneuritis Landry s paralysis Guillain Barré syndrome acute polyneuritis with facial diplegia polyradiculoneuritis) is confined to the peripheral nervous system and is usually characterized by symmetric ascending motor weakness areflexia distal sensory impairment and albuminocytologic dissociation of the spinal fluid The various designations given above are felt to be different names for the same condition first described by Landry in 1859 Although the clinical picture may vary considerably the pathologic changes are relatively constant When death occurs a week or more following the onset of symptoms there is marked degeneration of spinal nerves roots and ganglions with infiltration of inflammatory cells There is no evidence that the process extends to the central nervous system In view of the acute nature of the disease and the inflammatory character of the lesions an infectious etiology has been assumed but no evidence of virus or other infectious agent has been demonstrated

The condition usually begins within a week or two following an acute febrile illness most commonly an upper respiratory infection In some cases there is no history of prior illness Initial symptoms usually develop rapidly symmetric weakness of the lower extremities is accompanied by paresthesias in the fingers and toes Over a period of several days to a week weakness may progress to involve the trunk upper extremities face and bulbar muscles In the extremities both the distal and the proximal muscle groups are involved However the degree of weakness is variable at times reaching almost total voluntary paralysis Although the lower extremities tend to be involved first followed by upward spread of paralysis occasionally the arms or the muscles supplied by cranial nerves may be affected initially There is usually some impairment of position and vibratory sensation in the toes and fingers with relative sparing of other sensory modalities Pain is usually not a prominent symptom but in some cases it may be conspicuous and there may be tenderness of muscles and nerve trunks The muscles become flaccid and the tendon reflexes disappear as weakness increases Sphincter impairment is uncommon but transitory urinary retention may occur The motor weakness reaches a peak and remains unchanged for days or weeks If the patient survives the initial acute phase the prognosis for recovery is good and improvement once started usually progresses rapidly although occasionally convalescence may be prolonged During the acute phase mortality due to respiratory and vasomotor paralysis is as high as 30 per cent A characteristic finding in the spinal fluid is an elevated protein with a normal cell count (albuminocytologic dissociation) This spinal fluid formula appears in most cases but occasionally the protein is not elevated and rarely there is a significant number of lymphocytic cells in the spinal fluid There is usually a moderate polymorphonuclear leukocytosis in the peripheral blood

Acute idiopathic polyneuritis must be distinguished from other acute affections of peripheral nerves and roots poliomyelitis and acute ascending myelitis Postdiphtheritic polyneuritis produces a somewhat similar picture and may be identified by the recent history of diphtheria and transitory paralysis of palate or accommodation A positive Schick test is evidence against a preceding diphtheritic infection Acute porphyric polyneuropathy is distinguished by a recent history of abdominal symptoms normal spinal fluid protein and presence of porphyrins in the urine In acute idiopathic polyneuritis the features of acute onset following a febrile episode the rapid development of symptoms and the more prominent involvement of motor nerve fibers can help distinguish it from deficiency and toxic forms of polyneuropathy Meningeal carcinomatosis with multiple involvement of nerve roots is characterized by less acute onset steady progression of symptoms and frequently by inflammatory and neoplastic cells in the spinal fluid Poliomyelitis is distinguished by the asymmetric paralysis absence of sensory impairment and by the pleocytosis of the cerebrospinal fluid Acute ascending myelitis may cause widespread flaccid paralysis but in this condition sphincter disturbance is usually severe sensory loss is more extensive involving the whole body below the level of the cord lesion and plantar responses are later extensor

nervous system is largely unexplored In some diseases the primary disorder appears to be a direct affection of Schwann cells and the myelin sheath segments which they control (diphtheria toxin) In others the sensory and motor nerve cells are involved and changes in the myelin sheath may be secondary (beriberi?) Inflammatory or other alterations in the connective tissues of the nerves may be the mechanism of another type of peripheral neuropathy (lupus erythematosus?) Ischemia resulting from occlusion of the nutrient arteries e g polyarteritis nodosa is still another mode of nerve fiber damage Stretch laceration compression and other mechanical factors are operative in injuries of peripheral nerves

There is often a remarkable discrepancy between the degree of functional impairment before death and the degree of nerve fiber degeneration at autopsy particularly in the acute cases With complete paralysis there may be degeneration of only a few fibers or nearly every one may be involved This fact undoubtedly explains differences in the recovery rate from acute polyneuropathy

CLASSIFICATION

PRINCIPAL CAUSES OF PERIPHERAL NEUROPATHY

I Polyneuropathy (generalized neuropathy)
- A Poisons
  1. Metals arsenic lead mercury antimony bismuth copper phosphorus thallium
  2. Organic substances carbon monoxide carbon disulfide trichloroethylene methyl alcohol triorthocresylphosphate immune serums benzene and derivatives
- B Deficiency states and metabolic disorders chronic alcoholism beriberi pellagra combined system disease pregnancy chronic gastrointestinal disease carcinoma of lung diabetes mellitus porphyria amyloid disease
- C Infections
  1. Acute idiopathic polyneuritis (acute febrile polyneuritis of Osler Landry Guillain Barre syndrome)
  2. Polyneuropathy complicating acute or chronic infection diphtheria Boeck s sarcoid infectious mononucleosis
  3. Local infection of nerves leprosy
- D Vascular disease polyarteritis nodosa arteriosclerosis
- E Familial polyneuropathy progressive hypertrophic polyneuropathy peroneal muscular atrophy
- F Polyneuropathy of obscure origin chronic progressive or recurrent polyneuropathy

II Mononeuropathy (localized neuropathy)
- A Infections diphtheria leprosy herpes zoster sarcoid local sepsis
- B Trauma including stretching laceration and contusion external pressure compression by tumor herniated disk or cervical rib injection of medication into nerve
- C Tumors neurofibroma neurofibrosarcoma von Recklinghausen s neurofibromatosis
- D Idiopathic Bell s palsy brachial and sciatic neuritis
- E Serum neuritis
- F Vascular disease polyarteritis nodosa

GENERAL SYMPTOMS AND SIGNS OF POLYNEUROPATHY

Multiple peripheral nerve involvement is characterized by varying degrees of symmetric or asymmetric sensory impairment and motor weakness as a rule most pronounced over the distal portions of the extremities

Numbness and tingling of the hands and feet are frequent subjective symptoms They are variously described as prickling formication and "sleepy feeling in medical terminology they are called *paresthesias* They nearly always indicate involvement of fibers which convey the senses of touch vibration and position and impairment of these sensory modalities is usually found The skin may be exquisitely tender to touch pressure and pricking or pinching which produce a disagreeable sensation (dysesthesia) lasting for some time after the removal of the stimulus Marked tenderness to palpation over nerve trunks or muscles is common There may be hyperpathia or excessive reaction with raised threshold to painful stimulation and persistence of severe discomfort after removal of the stimulus Some degree of objective sensory impairment in the extremities is usually present Perception of light touch and pain is characteristically impaired in a distal distribution sometimes referred to as glove and stocking but is unlike hysterical sensory loss in that there is a gradual change to normal sensation proximally Position and vibratory sensation are diminished in the toes and fingers to varying degrees and these changes underlie the sensory ataxia and stereoanesthesia commonly observed with involvement of these modalities Impairment of temperature sensation frequently occurs and heat or cold may produce altered disagreeable sensations i e burning painful coldness (thermal dysesthesias)

Muscular weakness varies from slight involvement of distal muscle groups to complete symmetric paralysis of all muscles in the extremities and face In milder forms of weakness foot and wrist drop are common Muscle groups involved become flabby and undergo atrophy fairly rapidly Of the muscles innervated by cranial nerves bilateral facial involvement is most frequent followed by paralysis of bulbar muscles i e tongue pharynx larynx

The arms are infrequently involved The reflexes in the legs are sluggish or absent The spinal fluid protein is frequently elevated without increase in the cell count There is rarely a generalized polyneuropathy involving all extremities and producing symmetric atrophy weakness and sensory impairment A mononeuritic form of diabetic neuropathy may occur in which single nerve trunks are involved e g sciatic or femoral with symptoms referable to the distribution of the involved nerve Involvement of autonomic nerves occurs occasionally resulting in the loss of sweating impaired vasomotor control dependent edema gastrointestinal disturbance and sphincter impairment Cranial nerve lesions may occur unilateral third or sixth nerve palsy being most frequent but this is nearly always an isolated phenomenon unrelated to peripheral neuropathy The pathogenesis is unknown Vitamin deficiency or the vascular changes of Kimmelstiel Wilson disease have been suggested as the basis of the pathologic changes but are unproved The prognosis for improvement of diabetic neuropathy is usually good Treatment consists in rigid control of the diabetes with maintenance of relatively normal levels of blood sugar Vitamin supplements of the B group are usually added Pregnant mammalian liver extract has been ineffective in the experience of the authors

Porphyric Polyneuropathy Acute porphyria is characterized by the sudden development of abdominal cramps vomiting constipation fever tachycardia hypertension and leukocytosis During the height of these symptoms the urine changes to a burgundy color on exposure to light this is at least partly because of the conversion of porphobilinogen to uroporphyrin Toxic delirium and convulsions may occur during the phase of abdominal symptoms Many patients have recurrent attacks of abdominal pain without neurologic manifestations Shortly after the abdominal crisis signs of polyneuropathy may appear with rapidly developing flaccid paralysis of the legs and arms extending at times to involve the bulbar muscles Pains and paresthesias in the extremities are common and there is often objective sensory impairment Uroporphyrin is present in the urine and can be demonstrated by a pinkish fluorescence under ultraviolet light The presence of urinary porphobilinogen can be demonstrated by the Watson test The mortality in cases of polyneuropathy in porphyria is as high as 50 per cent and is due to bulbar or respiratory paralysis The involved nerves demonstrate acute degenerative lesions with little interstitial reaction Treatment is limited to symptomatic measures although cortisone or ACTH may be of value Barbiturates are contraindicated and other drugs should be used cautiously to avoid accentuation of symptoms

Amyloid Polyneuropathy Primary amyloidosis is a rare condition in which amyloid is deposited in blood vessels connective tissue and (rarely) in nerves A clinical picture of slowly progressive sensorimotor polyneuropathy is produced which may resemble beriberi or hypertrophic polyneuropathy Electrocardiographic changes and anemia are found in some patients The diagnosis is established by finding amyloid in a biopsy of skin and muscle Many of these cases have a plasmocytoma or multiple myeloma The clinical picture must be distinguished from that of a toxic polyneuropathy due to stilbamidine treatment or a compression myelopathy (myelomatous paraplegia)

Vascular Disease

Polyneuropathy Associated with Periarteritis Nodosa Multiple ischemic involvement of peripheral nerves secondary to damage to nutrient arteries occurs frequently in periarteritis nodosa Occasionally only single nerves may be involved resulting in mononeuropathy with sensory and motor symptoms restricted to the distribution of the damaged nerve Usually the nerves are involved diffusely and produce a clinical picture of subacute polyneuropathy with pain muscular wasting areflexia and peripheral sensory impairment Although at times symmetric in distribution its most distinctive features are its asymmetry and its intermittently progressive course The neurologic manifestations occur in association with the usual syndrome of fever cachexia hypertension abdominal pain focal visceral symptoms and eosinophilia See Chap 262 for treatment

Poisons

Arsenical Polyneuropathy Polyneuropathy resulting from chronic arsenical poisoning is relatively infrequent The involved nerves show nonspecific degenerative changes The symptoms develop rather slowly and are of both sensory and motor type like those of alcoholic polyneuropathy Pain and paresthesias in the legs and feet are prominent Weakness in the lower extremities is more pronounced than in the upper ones Disturbance of the mental functions convulsions and coma due to arsenical encephalopathy may occur The subacute course of the illness in conjunction with certain other findings is of importance in diagnosis These other findings include gastrointestinal irritation brownish cutaneous pigmentation most marked about normally pigmented areas hyperkeratosis of the palms and soles and white transverse bands in the nails (Mees lines) anemia and signs of liver disease The diagnosis is confirmed by demonstration of arsenic in the hair nails urine or feces Treatment consists of withdrawal from exposure and administration of BAL in doses of 3 mg per kg body

The treatment is symptomatic with the use of the respirator in the acute phase if respiratory paralysis occurs Adrenal steroids have been used in a few cases with encouraging results but have had no effect in others A trial of these hormones is indicated in critically ill patients in a dosage of 300 mg per day for 2 days and 150 mg daily thereafter for at least 2 to 3 weeks (Meticorten 25 to 30 mg per day)

Diptheritic Polyneuritis In the course of diphtheria various localized neuritic manifestations occur early in the disease and may be followed by the later development of generalized polyneuritis with degenerative changes in the spinal ganglions roots and peripheral nerves These complications occur more frequently in children than in adults Palatal paralysis occurs during the second or third week and occasionally earlier It is characterized by nasal speech and regurgitation of fluids through the nose Paralysis of accommodation with inability to focus on near objects may occur at the same time During the fifth to seventh weeks of the illness generalized sensorimotor polyneuritis develops but it may be delayed up to 2 or 3 months from the onset of diphtheria It may occur without evidence of a preceding pharyngitis or localized neuritis The progression and course of diphtheritic polyneuritis are similar in many respects to those of idiopathic polyneuritis and clinically it may be difficult to distinguish between the two conditions The generalized symptoms and signs progress for a week or two then become stationary and gradually subside The lower limbs tend to be more involved than the upper and distal muscle weakness is more pronounced than proximal Paresthesias in the fingers and toes are prominent and sensory impairment conforms to a distal distribution Position sense is often greatly impaired The tendon reflexes disappear The spinal fluid protein is usually elevated and always without increase in cells Improvement usually begins within a few weeks but may be delayed for months Prognosis for complete recovery is usually good Fatalities have usually been due to myocarditis or respiratory paralysis Treatment is symptomatic Administration of antitoxin is of no value once paralysis has developed Antitoxin given within several days of the onset of diphtheria usually prevents the development of polyneuritis

Pink Disease (Erythredema Polyneuropathy) This syndrome of obscure etiology occurs in young children and is characterized by chronic polyneuropathy with generalized weakness muscular hypotonia areflexia and distal sensory impairment Typical associated findings are swelling and erythema of the face hands trunk and feet irritability insomnia anorexia alopecia and trophic changes of the skin Fever is usually absent The peripheral nerves show degenerative changes Improvement occurs slowly over a period of months Treatment is symptomatic with vitamin supplements on the assumption that the condition may represent a deficiency disease A similar clinical picture has been produced by mercury intoxication in children In some of these cases rapid improvement resulted following administration of BAL

Leprous Polyneuritis In leprosy there is marked irregular thickening of peripheral nerves owing to formation of leprous nodules i e aggregations of inflammatory cells and Hansen bacilli surrounded by a connective tissue capsule Secondary degeneration of myelin and axones occurs Multiple peripheral nerves are involved producing symmetric distal weakness and sensory impairment Leprous nodules in the skin of the face are common and in many cases there is facial anesthesia Trophic changes with necrosis of phalanges are observed in some patients The greatly thickened nodular nerves are frequently palpable The diagnosis can be proved by demonstrating bacilli in nasal scrapings or by biopsy of a leprous nodule

Deficiency and Metabolic Disorders

Alcoholic Polyneuropathy This is described in Chap 99 Alcohol Other conditions caused by thiamine deficiency are beriberi polyneuropathy of pregnancy and chronic deficiency syndromes due to gastrointestinal disease The symptoms of polyneuropathy in these conditions are similar to those encountered in the alcoholic variety

Polyneuropathy due to degeneration of peripheral nerves occurs also in pellagra and is said to occur in combined system disease The latter responds to administration of liver extract or vitamin B_1

Recently cases of sensory and sensorimotor polyneuropathy have been discovered in association with bronchogenic carcinoma and multiple myeloma The mechanism of the neuropathy in these conditions is obscure

Diabetic Polyneuropathy About 50 per cent of older diabetic patients have a mild and relatively asymptomatic neuropathy with absent ankle jerks and impaired vibratory sensation in the toes as the only signs Symptomatic neuropathy on the other hand occurs in about 4 per cent of diabetic patients and is more frequent among patients with poorly controlled diabetes i e prolonged hyperglycemia and weight loss There are burning tearing or lancinating pains in the calves and paresthesias in the feet The pains occur frequently during the night Motor weakness is not prominent in some cases but dominates the clinical picture in others (diabetic amyotrophy) Sensory impairment involves mainly pain with only slight loss of touch and pressure sensation Occasionally vibratory and position senses alone may be impaired (diabetic tabes)

DIAGNOSIS OF POLYNEUROPATHY

In the differential diagnosis the first problem is to determine whether the disease is spinal muscular or neural The characteristic symmetric involvement of the extremities muscle and nerve tenderness distal sensory impairment areflexia, muscle atrophy trophic skin changes and absence of sphincter impairment are distinguishing features of polyneuropathy Pain ataxia and loss of reflexes in the lower limbs occur in tabes but unlike polyneuropathy there is no motor paralysis muscle tenderness or atrophy and lightning pains Argyll Robertson pupils bladder disturbances and serologic tests set it apart

Poliomyelitis is distinguished by the absence of objective sensory disturbance and by the presence of segmental rather than peripheral distribution of muscle paralysis asymmetry of paralysis evidence of meningeal irritation and spinal fluid pleocytosis *Trichinosis* may simulate polyneuropathy because of muscle tenderness and weakness but is distinguished by the periorbital edema preservation of tendon reflexes absence of sensory impairment and the presence of eosinophilia *Dermatomyositis* may be associated with pronounced muscle weakness but the weakness is usually proximal, there is no sensory impairment and the tendon reflexes are often preserved *A distal form* of myopathy may resemble chronic motor neuropathy and in some instances the differential diagnosis must depend on biopsy Many of the myopathic cases are familial *Acute myelitis* causes rapidly developing symmetric paralysis with sensory loss but may be distinguished from polyneuropathy by the presence of extensor plantar responses sensory impairment involving the whole body below the level of the lesion and severe sphincter disturbance Once the diagnosis of polyneuropathy is made the particular type must be determined by reference to the clinical features described above

LOCALIZED NEUROPATHY

The Common Brachial and Crural Mononeuropathies

Brachial Palsies The fifth to eighth cervical and first thoracic spinal nerves innervate the muscles of the shoulder girdles and upper extremities The brachial plexus is formed by components of these nerves and lesions of the nerves or their branches result in characteristic palsies The following are the brachial palsies most likely to be observed on the medical wards of a hospital

Long Thoracic Nerve This nerve is derived from the fifth sixth and seventh cervical nerves and supplies the serratus magnus muscle Paralysis of the serratus magnus muscle results in inability to raise the arm over the head from a forward position and there is winging of the inner border of the scapula on pushing forward against resistance It is injured most commonly by pressure on the shoulder from either a sudden blow or prolonged pressure from carrying heavy weights It is also involved at times in diabetic patients and as a manifestation of brachial or serum neuritis

Suprascapular Nerve This nerve is derived from the fifth and sixth cervical nerves and supplies the supra and infraspinatus muscles Lesions may be diagnosed from the presence of weakness of abduction and external rotation of the arm and atrophy of the supra and infraspinatus muscles The nerve may be injured by blows on top of the shoulder and fracture-dislocations of the shoulder joint.

Upper Brachial Plexus Paralysis This is due to injury to the fifth cervical nerve caused most commonly by forceful separation of the head and shoulder during difficult delivery or by pressure in the supraclavicular region during anesthesia. The muscles affected are the biceps deltoid brachialis anticus supinator longus supra and infraspinatus and rhomboids The arm hangs at the side internally rotated with the elbow extended The forearm is pronated Hand motion is unaffected The prognosis for spontaneous recovery is generally good especially in cases of birth injury This condition as a result of birth injury (Erb-Duchenne brachial plexus palsy) is discussed in Chaps 25 and 253

Lower Brachial Plexus Paralysis This is due to injury to the eighth cervical and first thoracic roots as a result of traction on the abducted arm in falls during operation and with tumors of the apex of the lung (superior sulcus or Pancoast syndrome) Injury may occur during birth (Dejerine-Klumpke brachial plexus injury) There are paralysis and wasting of the small muscles of the hand and a characteristic claw hand deformity Sensory loss is limited to the ulnar border of the hand and there may be an associated paralysis of the cervical sympathetic nerve with a Horner's syndrome

Lesions of the Cords of the Brachial Plexus The outer and inner cords are most commonly affected Dislocation of the head of the humerus pressure of the cervical rib and stab wounds are the most frequent causes Injury to the outer cord results in paralysis of the biceps and coracobrachialis muscles and all muscles supplied by the median nerve except the intrinsic hand muscles There is some loss of sensation over the radial aspect of the forearm Involvement of the inner cord as may occur in compression by cervical rib results in paralysis of the muscles supplied by the ulnar nerve together with the median innervated intrinsic muscles of the

weight every 4 to 6 hr for 3 days and then twice daily for 10 days The prognosis is usually good but depends on the duration of symptoms prior to treatment Recovery of motor power may require months or a year or more

Poisoning due to mercury thallium and antimony may also cause a polyneuropathy which may respond to the administration of BAL

Lead Neuropathy Lead neuropathy occurs following chronic exposure to lead and its most characteristic feature is the predominantly motor affection involving mainly the upper extremities The radial nerves are most frequently involved producing wrist and finger drop without sensory manifestations Less commonly weakness of proximal shoulder girdle muscle occurs and in the lower extremities foot drop may appear Clinically the paralyzed muscles are those which are most used Important associated findings are anemia basophilic stippling of red blood cells lead line along the gingival margins colicky abdominal pain and constipation Neuropathy occurs usually in adults and is infrequent in children In contrast lead encephalopathy manifested by increased intracranial pressure convulsions blindness and coma occurs more frequently in children The diagnosis of lead neuropathy is established by the history of lead intoxication the characteristic motor involvement associated findings and increased urinary excretion of lead Treatment consists of withdrawal from exposure to lead and measures to eliminate lead from the blood stream (see p 765) The prognosis for recovery of motor power is good although in chronic cases recovery may be slow (see p 766)

Triorthocresylphosphate Polyneuropathy (Jamaica Ginger Paralysis) Periodic outbreaks of *polyneuropathy have occurred because of ingestion* of triorthocresylphosphate The largest number of cases occurred in 1930 following consumption of adulterated extract of ginger Recent cases have occurred because of the contamination of cooking oil Pathologically there are degeneration of peripheral nerves and also destruction of white matter and anterior horn cells in the spinal cord The initial symptomatology is that of gastrointestinal irritation followed in about 10 days by the development of a severe motor neuropathy involving distal muscles Wrist and foot drop occur Pain is common but there is usually no sensory impairment Later extensor plantar reflexes appear In many cases the paralysis fails to improve The treatment is symptomatic

Familial Polyneuropathy

Peroneal Muscular Atrophy (Charcot Marie Tooth Disease) This is a hereditary disease with onset during adolescence or adult years There is chronic degeneration of peripheral nerves and roots resulting in distal muscle atrophy beginning in the feet and legs and later in the hands Early symptoms are muscular wasting and weakness affecting the extensor and abductor muscles of the feet and producing an equinovarus deformity Later all muscles below the middle third of the thigh may be affected resulting in a stork leg" appearance of the legs After a period of years atrophy of hand and forearm muscles develops The wasting never extends above the elbows or above the middle third of the thighs Perforating ulcers may occur in the feet Pain paresthesias and cramps are common The sensory disorder is usually rather slight Often there is some impairment of position and vibratory sensation in the feet and touch and pain sensation are lost in the feet in some cases Reflexes are lost in the involved limbs The progression of the illness is very slow and may be arrested at any stage (See Chap 259 for more complete description)

Progressive Hypertrophic Polyneuropathy (Dejerine Sottas Disease) This type of neuropathy is uncommon and is frequently familial It begins usually in childhood and is slowly progressive Pain and paresthesias in the feet are early symptoms followed by development of symmetric weakness and wasting of the distal portion of the limbs Sensation is impaired in a distal distribution and the tendon reflexes are absent Miotic pupils nystagmus and kyphoscoliosis have been observed in some cases A characteristic finding is the enlargement of the peripheral nerves because of hypertrophy and proliferation of the cells of the sheath of Schwann and fibroblasts Palpable thickening of the ulnar and peroneal nerves may be conspicuous *In the absence of palpable enlargement* of nerves the diagnosis can be established by biopsy of a cutaneous nerve The treatment is symptomatic

Polyneuropathy of Obscure Origin

Chronic Progressive Polyneuropathy Not infrequently one encounters patients with a slowly progressive polyneuropathy in whom no etiologic factor can be found There are weakness and wasting of the limbs areflexia and peripheral sensory impairment Pain is less prominent than in the acute forms of neuropathy and is often absent altogether Progression occurs over a period of months occasionally with fatal termination but may be followed by recovery or arrest of the condition The peripheral nerves show evidence of widespread degeneration Without knowledge of etiology and lacking a specific therapy one can only resort to the usual symptomatic treatment of polyneuropathy A course of BAL may be tried on empirical grounds

Femoral Nerve This nerve is derived from the second third and fourth lumbar nerves It supplies the iliacus pectineus sartorius and quadriceps muscles and carries sensory impulses from the anteromedial aspect of the thigh and medial side of the lower leg Following injury to the nerve there is paralysis of extension of the knee with wasting of the quadriceps muscle and also some weakness of hip flexion The knee jerk is abolished The nerve may be involved in fractures and dislocation of the hip and in fractured pelvis It may be affected in diabetes polyarteritis nodosa and in retroperitoneal pelvic or abdominal lesions such as psoas abscess or tumor Because of the proximity of the femoral artery to the nerve in the femoral triangle wounds in this region may be fatal

Sciatic Nerve This nerve is derived from the fourth and fifth lumbar and first second and third sacral nerves It provides the motor innervation of the hamstring muscles and all those below the knee and it carries sensory impulses from the posterior aspect of the thigh and posterior and lateral aspects of the leg and entire sole In complete sciatic paralysis the knee cannot be flexed and all muscles below the knee are paralyzed The sciatic nerve is commonly injured in fractures of the pelvis or femur and in gunshot wounds of the buttock and thigh It may also be involved by pelvic tumors and in both diabetes mellitus and polyarteritis nodosa Cryptogenic forms also occur and are actually more frequent than the identifiable types of disease A ruptured lumbar disk often simulates sciatic neuropathy Incomplete lesions of the sciatic nerve occasionally result in causalgia

Common Peroneal Nerve This nerve is one of the terminal divisions of the sciatic nerve in the popliteal fossa It supplies the dorsiflexors of the foot and toes and everters of the foot, and sensation to the dorsum of the foot and lateral aspect of the lower half of the leg These functions are lost with lesions which completely interrupt the nerves Pressure or sleep palsy is one of the most frequent types of injury the compression being of that part of the nerve which passes over the head of the fibula It is also commonly involved by fractures involving the upper end of the fibula and in diabetic polyarteritis

Tibial Nerve This nerve is the other of the two terminal divisions of the sciatic nerve in the popliteal fossa It supplies all the calf muscles and the flexors of the foot Complete paralysis of the nerve results in a calcaneovalgus deformity of the foot which no longer can be plantar flexed There is loss of sensation over the plantar aspect of the foot

The Diseases Which Involve Single Nerves or Plexuses

Infections In faucial diphtheria selective involvement of the vagi and nerves to the ciliary muscles of the eye results in palatal paralysis and paralysis of accommodation The palatal palsy occurs in the first 2 weeks of infection and the loss of accommodation about a week later Both tend to improve rapidly In cutaneous diphtheria involvement of nerves locally results in paralysis of the muscles supplied by the spinal segment from which the infected region is innervated In leprosy granulomatous infection of multiple peripheral nerves usually takes place simultaneously producing symptoms of polyneuritis rather than localized asymmetric neuritis but the latter may be found in the early stages of leprous neuritis Herpes zoster is a sensory neuritis of virus etiology characterized by acute inflammation of one or more posterior root ganglions spinal nerves and roots and gray matter of the spinal cord Lancinating pain and hyperalgesia over the skin surface supplied by affected roots occur for 3 or 4 days followed by the appearance of a segmental herpetic eruption. If the inflammatory process spreads to involve adjacent motor roots of anterior horns of the cord segmental motor weakness and wasting appear Paralysis of the oculomotor nerves may occur in conjunction with involvement of the gasserian ganglion (ophthalmoplegic zoster) Facial paralysis may occur with involvement of the geniculate ganglion (Ramsay Hunt syndrome) but has accompanied zoster of other ganglions as well. Sarcoidosis can involve single or multiple peripheral nerves producing asymmetric mononeuritis or polyneuritis Unilateral or bilateral facial paralysis is common in association with parotitis and uveitis in sarcoidosis

Trauma External trauma may result in complete transection of a peripheral nerve or may impair conduction without interrupting the anatomic continuity of the involved nerve Complete division of a mixed peripheral nerve results in paralysis and sensory loss corresponding to the region supplied by the damaged nerve Recovery of function after complete division can take place only when the divided ends lie in apposition or have been sutured Growth of nerve fibers from the central end proceeds at a rate of 1 to 2 mm a day and the recovery time can be estimated by the distance between the site of injury and destination of the nerve An early indication of regeneration is the presence of tingling sensation on tapping the nerve below the lesion (Tinel's sign) Sensory recovery precedes the return of motor power All forms of cutaneous sensation begin to return together Appreciation of pain and temperature improves but the stimuli are poorly localized for some time Eventually there is recovery of the discriminative aspects of sensation, including localization of sensory stimuli, postural sense recognition of slight differences in temperature and appreciation of very light touch

hand and sensory loss over the ulnar aspect of the hand and forearm

Axillary Nerve This nerve arises from the posterior cord of the brachial plexus and supplies the teres minor and deltoid muscles It may be involved in injuries resulting from fractures of the neck of the humerus serum neuritis brachial neuritis or is part of a disease of unknown etiology The anatomic localization depends on the recognition of a paralysis of abduction of the arm wasting of the deltoid muscle and slight impairment of sensation over the outer aspect of the shoulder

Musculocutaneous Nerve This nerve is derived from the fifth and sixth cervical nerves and is a branch of the outer cord of the brachial plexus It innervates the biceps and brachialis anticus muscles Lesions of the nerve result in weakness of elbow flexion This nerve is rarely injured alone

Radial Nerve This nerve is derived from the fifth to eighth cervical nerves and is the termination of the posterior cord of the brachial plexus It innervates the triceps muscle and the supinator and extensor muscles of the forearm and hand Complete radial paralysis results in inability to extend the elbow paralysis of supination of the forearm and complete wrist and finger drop Sensation is impaired over the posterior aspect of the forearm and a small area over the radial aspect of the dorsum of the hand The nerve may be injured in the axilla for example in crutch palsy but is most commonly injured in the lower arm where the nerve winds around the humerus Common types of injury at this site are fractures and pressure palsies during sleep

Median Nerve This nerve is derived from the sixth cervical to the first thoracic nerves and is formed by the union of two heads from the inner and outer cords of the brachial plexus It innervates the pronators of the forearm long finger flexors and abductor and opponens muscles of the thumb and is a sensory nerve to the palmar aspect of the hand Complete median nerve paralysis results in wasting of the affected muscles and inability to pronate the forearm or deviate the hand in an ulnar direction paralysis of flexion of the index finger and terminal phalanx of the thumb weakness of flexion of the remaining fingers weakness of abduction and opposition of the thumb and sensory impairment over the radial two thirds of the palmar aspect of the hand and over the distal phalanges of the dorsum of the index and third fingers The nerve may be injured in the axilla by shoulder dislocation and at any part of its course by laceration stab or gunshot wounds The wrist is the most common site of external injury Compression of the nerve at the wrist (carpal tunnel syndrome) may occur secondary to prolonged occupational pressure or local infiltration for example by a thickening of connective tissue and deposit of amyloid with multiple myeloma Incomplete lesions of the median nerve between the axilla and wrist may result in *causalgia*

Ulnar Nerve This nerve is derived from the eighth cervical and first thoracic nerves It innervates the ulnar flexor of the wrist the inner half of the deep finger flexors the adductors and abductors of the fingers adductor of the thumb the two medial lumbricales and muscles of the hypothenar eminence It is the sensory nerve to the fifth and ulnar half of the fourth fingers and ulnar border of the hand Complete ulnar paralysis results in a characteristic claw hand deformity owing to wasting of the small hand muscles and hyperextension of the fingers at the metacarpophalangeal joints and flexion at the interphalangeal joints The flexion deformity is most pronounced in the fourth and fifth fingers Sensory loss occurs over the fifth finger the ulnar aspect of the fourth finger and the ulnar border of the palm The ulnar nerve is most commonly injured at the elbow because of fracture or dislocation involving the joint *Delayed ulnar palsy* may occur many years after an injury to the elbow joint which has resulted in a cubitus valgus deformity of the joint Because of the deformity the nerve is stretched in its course over the ulnar condyle The superficial location of the nerve at the elbow makes it a common site of pressure palsy Prolonged pressure on the outer part of the palm may result in damage to the deep palmar branch of the ulnar nerve causing weakness of small hand muscles but no sensory loss

Crural Palsies The twelfth thoracic first to fifth lumbar and first second and third sacral spinal nerve roots compose the lumbosacral plexuses and innervate the muscles of the lower extremities and saddle region The following are the common crural palsies

Lateral Femoral Cutaneous Nerve This nerve is derived from the second and third lumbar nerves It is a sensory nerve supplying the lateral aspect of the thigh The nerve enters the thigh beneath the lateral end of the inguinal ligament and then enters the fascia lata where it may become constricted Compression of the nerve results in uncomfortable paresthesias along its cutaneous distribution and in sensory impairment The condition is called *meralgia paresthetica* (mentioned below)

Obturator Nerve This nerve is derived from the second third and fourth lumbar nerves It supplies the adductor muscles of the thigh and injury to the nerve results in almost complete paralysis of adduction of the thigh The nerve is most frequently injured during the course of a difficult labor and also as a result of dislocation of the hip or an obturator hernia It may be affected in diabetes polyarteritis nodosa retroperitoneal cervical carcinoma and other tumors etc

Femoral Nerve This nerve is derived from the second third and fourth lumbar nerves It supplies the iliacus pectineus sartorius and quadriceps muscles and carries sensory impulses from the anteromedial aspect of the thigh and medial side of the lower leg Following injury to the nerve there is paralysis of extension of the knee with wasting of the quadriceps muscle and also some weakness of hip flexion The knee jerk is abolished The nerve may be involved in fractures and dislocation of the hip and in fractured pelvis It may be affected in diabetes polyarteritis nodosa and in retroperitoneal pelvic or abdominal lesions such as psoas abscess or tumor Because of the proximity of the femoral artery to the nerve in the femoral triangle wounds in this region may be fatal

Sciatic Nerve This nerve is derived from the fourth and fifth lumbar and first second and third sacral nerves It provides the motor innervation of the hamstring muscles and all those below the knee and it carries sensory impulses from the posterior aspect of the thigh and posterior and lateral aspects of the leg and entire sole In complete sciatic paralysis the knee cannot be flexed and all muscles below the knee are paralyzed The sciatic nerve is commonly injured in fractures of the pelvis or femur and in gunshot wounds of the buttock and thigh It may also be involved by pelvic tumors and in both diabetes mellitus and polyarteritis nodosa Cryptogenic forms also occur and are actually more frequent than the identifiable types of disease A ruptured lumbar disk often simulates sciatic neuropathy Incomplete lesions of the sciatic nerve occasionally result in causalgia

Common Peroneal Nerve This nerve is one of the terminal divisions of the sciatic nerve in the popliteal fossa It supplies the dorsiflexors of the foot and toes and everters of the foot and sensation to the dorsum of the foot and lateral aspect of the lower half of the leg These functions are lost with lesions which completely interrupt the nerves Pressure or sleep palsy is one of the most frequent types of injury the compression being of that part of the nerve which passes over the head of the fibula It is also commonly involved by fractures involving the upper end of the fibula and in diabetic polyarteritis

Tibial Nerve This nerve is the other of the two terminal divisions of the sciatic nerve in the popliteal fossa It supplies all the calf muscles and the flexors of the foot Complete paralysis of the nerve results in a calcaneovalgus deformity of the foot which no longer can be plantar flexed There is loss of sensation over the plantar aspect of the foot

The Diseases Which Involve Single Nerves or Plexuses

Infections In faucial diphtheria selective involvement of the vagi and nerves to the ciliary muscles of the eye results in palatal paralysis and paralysis of accommodation The palatal palsy occurs in the first 2 weeks of infection and the loss of accommodation about a week later Both tend to improve rapidly In cutaneous diphtheria involvement of nerves locally results in paralysis of the muscles supplied by the spinal segment from which the infected region is innervated In leprosy granulomatous infection of multiple peripheral nerves usually takes place simultaneously producing symptoms of polyneuritis rather than localized asymmetric neuritis but the latter may be found in the early stages of leprous neuritis Herpes zoster is a sensory neuritis of virus etiology characterized by acute inflammation of one or more posterior root ganglions spinal nerves and roots and gray matter of the spinal cord Lancinating pain and hyperalgesia over the skin surface supplied by affected roots occur for 3 or 4 days followed by the appearance of a segmental herpetic eruption If the inflammatory process spreads to involve adjacent motor roots of anterior horns of the cord segmental motor weakness and wasting appear Paralysis of the oculomotor nerves may occur in conjunction with involvement of the gasserian ganglion (ophthalmoplegic zoster) Facial paralysis may occur with involvement of the geniculate ganglion (Ramsay Hunt syndrome) but has accompanied zoster of other ganglions as well Sarcoidosis can involve single or multiple peripheral nerves producing asymmetric mononeuritis or polyneuritis Unilateral or bilateral facial paralysis is common in association with parotitis and uveitis in sarcoidosis

Trauma External trauma may result in complete transection of a peripheral nerve or may impair conduction without interrupting the anatomic continuity of the involved nerve Complete division of a mixed peripheral nerve results in paralysis and sensory loss corresponding to the region supplied by the damaged nerve Recovery of function after complete division can take place only when the divided ends lie in apposition or have been sutured Growth of nerve fibers from the central end proceeds at a rate of 1 to 2 mm a day and the recovery time can be estimated by the distance between the site of injury and destination of the nerve An early indication of regeneration is the presence of tingling sensation on tapping the nerve below the lesion (Tinel's sign) Sensory recovery precedes the return of motor power All forms of cutaneous sensation begin to return together Appreciation of pain and temperature improves but the stimuli are poorly localized for some time Eventually there is recovery of the discriminative aspects of sensation including localization of sensory stimuli postural sense recognition of slight differences in temperature and appreciation of very light touch

Pressure Palsy This results in temporary paralysis owing to local compression Mild degrees of compression are followed by fairly rapid recovery Severe compression such as may occur during a bout of alcoholic intoxication deep sleep or anesthesia may result in focal disintegration of myelin damage to axis cylinders and Wallerian degeneration of distal segments Recovery is slow and must await regeneration Common varieties of pressure palsy are radial nerve paralysis with wrist drop due to prolonged pressure against the back of the arm (Saturday night palsy) ulnar palsy due to repeated trauma to the nerve at the elbow especially after an old fracture that changes the relation of the nerve to the bicipital groove and peroneal nerve palsy with foot drop caused by compressing the nerve against the fibula as in sitting with legs crossed or during obstetric procedures with legs in stirrups

Meralgia paresthetica is a sensory neuropathy characterized by pain and paresthesia over the lateral aspect of the thigh because of compression of the lateral femoral cutaneous nerve in the fascia lata Pressure on nerve roots in the cervical and lumbar regions by *herniated intervertebral disks* results in pain sensory impairment and variable motor weakness corresponding to the area supplied by the involved root Compression of the inner cord of the brachial plexus by a *cervical rib or by some other malformation of the thoracic outlet* (thoracic outlet syndrome) results in atrophy of small hand muscles and sensory impairment over the ulnar and sometimes median nerve distribution The median nerve may be compressed at the wrist beneath the transverse carpal ligament (carpal tunnel syndrome) There are pain and paresthesias in the palmar surface of the hand and first three fingers thenar atrophy weakness in flexor of thumb and opponens muscle and sensory impairment over the median nerve distribution

Tumor Peripheral nerves may be compressed or invaded by primary or metastatic tumors arising in other tissues Solitary tumors of nerve sheaths or neuromas commonly occur along the roots of spinal nerves chiefly in the thoracic and lumbar regions Compression of the nerve root and adjacent spinal cord may occur Root compression causes pain referred to the distribution of the involved nerve and there may be associated sensory impairment and motor weakness Lymphomatosis and carcinomatosis of the cranial and spinal meninges may implicate single or multiple cranial and spinal nerve roots and give rise to confusing clinical syndromes Tumor cells may be found in the cerebrospinal fluid Solitary neuromas may involve any of the peripheral nerves producing local pain and tenderness to palpation Multiple neuromas occur in von Recklinghausen s disease and are associated in this condition with multiple congenital anomalies as well as kyphoscoliosis cutaneous pigmentation and cutaneous fibromas The treatment of solitary expanding nerve tumors of the limbs is wide excision with nerve graft or suture if that is possible

Idiopathic Neuropathy *Bell's palsy* is due to compression of the facial nerve in the fallopian canal as a result of an acute inflammatory process involving the nerve Edema leads to compression of nerve fibers with resulting unilateral paralysis of facial muscles (see p 267)

Brachial neuritis is an acute affection of the brachial plexus characterized by the acute or subacute onset of severe pain in the neck arm and hand followed by moderate muscle weakness slight impairment of sensation in the fingers and hand numbness or hyperesthesia and depressed reflexes in the involved arm The pain is usually severe and constant and is aggravated by moving the arm or stretching the brachial plexus Muscle wasting is rarely severe but some cases of brachial neuritis especially those described by the term *neuralgic amyotrophy* may be followed by localized paralysis and atrophy of the shoulder girdle and arm muscles Recovery slowly occurs over a period of several weeks to months Symptomatic treatment including complete rest of the involved arm and analgesics in the acute phase followed by mild massage and exercise usually suffices

Sciatic neuritis causes pain in the lumbar region and behind the leg from buttock to ankle The pain is aching or burning in quality and is aggravated by movement or straining The sciatic nerve is tender to palpation or stretching There may be slight weakness of the hamstrings and muscles below the knee The ankle jerk is absent Sensory impairment is usually slight It is necessary to distinguish the symptoms of sciatic neuritis from those of sciatic compression In compression (e g by tumor) the onset is more gradual symptoms are progressive muscle wasting is more conspicuous the nerve is less tender to palpation and sensory loss is greater The course of sciatic neuritis is stationary at first followed by slow improvement Treatment is symptomatic

Serum neuritis develops several days after the onset of serum sickness The fifth cervical nerve is most commonly involved with pain paralysis and atrophy corresponding to the distribution of the nerve Occasionally the entire brachial plexus may be involved and there is sometimes but rarely a generalized polyneuritis The etiology is not known but is attributed to perineural edema comparable to the urticaria of serum sickness with compression of affected roots or nerves Recovery is usually complete but occurs slowly

TREATMENT

In addition to measures already mentioned general principles in the treatment of polyneuropathy include removal of any known toxic factor correction of nutritional deficiency rest of affected nerves and muscles maintenance of muscle tone by heat massage and electrical stimulation and the prevention of joint fixation and contractures Bed rest is indicated for generalized weakness to relax involved muscles and to avoid cardiac strain Pain in the acute stage is relieved by analgesics and the use of moist hot packs if tolerated Pressure of bedclothes is avoided by cradle support and foot drop is prevented by sand bags beneath the soles Passive movement and gentle massage are started as soon as tolerated in order to maintain tone and prevent contracture After the acute painful stage appropriate splints can be worn and more intensive physiotherapy carried out Adequate nutrition must be maintained with vitamin supplements of the B group added In the nutritional polyneuropathies a high calorie high vitamin diet with 50 mg thiamine daily and 15 Gm of brewer's yeast t i d are prescribed On the basis of blood pyruvate levels following glucose administration it is said that three main groups of peripheral neuropathy can be distinguished One group shows no impairment of pyruvate metabolism and is not affected by thiamine treatment In the second group there is a block in pyruvate oxidation that responds to thiamine and in the third group a block in pyruvate oxidation that is not changed by thiamine The latter group includes cases of arsenic intoxication which respond to treatment with BAL In cases of polyneuropathy of obscure origin in which pyruvate metabolism is impaired if there is no response to thiamine a short trial of BAL is indicated The authors have been unable to verify this subdivision of cases of polyneuropathy and the efficacy of the therapeutic methods which follow from it has not been verified

Treatment in localized neuropathy is directed toward maintaining tone and preventing stretching of paralyzed muscles preventing contractures and keeping joints mobile while nerve regeneration is taking place Heat massage passive movement and electrical stimulation are employed Operative repair is necessary in cases of complete nerve transection and surgical treatment is required in some but by no means all cases of chronic compression by tumor cervical rib or herniated intervertebral disk

Section 8 Diseases of Supporting Tissues Other Than Bone

Ivan L Bennett Jr

The next six chapters describe diseases that have in common the production of damage in the soft skeleton of the body the skin and connective tissues Although this categorization is somewhat arbitrary it possesses advantages Generally common or related etiology is the basis for classification and ideally similarity in manifestations is the most useful clinical criterion for grouping diseases Here we are dealing for the most part with diseases of obscure etiology many of the disorders are known

to occur in association with a variety of infections and hypersensitivity states Because injury to connective tissue can produce structural or functional abnormalities in almost any organ system or anatomic site *it is difficult to select a few predominant* symptoms and signs from the diversity of manifestations that can accompany such diseases and to rely on them is a logical starting point in grouping If they are considered by the clinician as generalized disorders of connective tissue however they are far less perplexing For example several genetically determined diseases once thought of as rare and esoteric syndromes composed of a peculiar hodgepodge of unrelated abnormalities are discussed in this section They are now known to be relatively common when viewed as disorders of connective tissue such associations as ectopia lentis inguinal hernia and dissecting aneurysm of the aorta in the Marfan syndrome or angioid streaks and melena in pseudoxanthoma elasticum are logical and expected

In addition to the major collagen vascular disorders several relatively unusual diseases of uncertain etiology that have closely related clinical or histologic manifestations are included polymyositis relapsing panniculitis and scleredema Because rheumatic fever and acute hemorrhagic nephritis are known to be related etiologically to group A streptococcal infection they are discussed in another part of the book as complications of streptococcal disease Both might well have been included in this section

The two most important afflictions of the joints rheumatoid arthritis and degenerative joint disease are included in this section along with a detailed discussion of the problem of arthritis Finally some of the fundamentals of clinical dermatology are presented from the point of view of the patient with skin disease or with systemic disease manifested by cutaneous lesions

261 HERITABLE DISORDERS OF CONNECTIVE TISSUE

Victor A McKusick

THE MARFAN SYNDROME

Definition The Marfan syndrome (synonyms arachnodactyly dolichostenomelia [long thin limbs] dystrophia mesodermalis congenita typus Marfanis etc) is a heritable generalized disorder of one element of connective tissue clinically manifested by abnormalities of the eye (especially ectopia lentis) of the skeletal system (especially excessive length of the long bones) and of the cardiovascular system (especially diffuse and/or dissecting aneurysm of the ascending aorta).

Clinical Manifestations *Skeleton* Characteristically the tubular bones are excessively long resulting in arachnodactyly and in anomalous proportions In the Marfan syndrome (Fig 199) the lower segment measurement (pubic symphysis to sole) which after puberty is normally about equal to the upper segment measurement is usually appreciably in excess of the upper segment measurement The arm span exceeds the height The patient with the Marfan syndrome is taller than the average for his age and family however the deviation from the normal skeletal proportion is of more specific diagnostic significance Excessive longitudinal growth of ribs may result in outward displacement of the sternum (pigeon breast pectus carinatum) or inward displacement (pectus excavatum *Trichterbrust*) Redundant ligaments tendons and joint capsules result in loose jointedness hyperextensibility of joints genu recurvatum (backward curvature of the legs at the knees) flat feet kyphoscoliosis and habitual dislocation of the hips patella clavicles mandible and other joints Hernia occurs with increased frequency In general patients with the Marfan syndrome display a sparsity of subcutaneous fat

Eye *Ectopia lentis* (subluxation of the lens dislocated lens) is the ocular hallmark of the Marfan syndrome Iridodonesis tremor of the iris is occasionally a clue to the presence of dislocated lenses Occasionally the margin of a dislocated lens is visible through the undilated pupil and occasionally there may be a total dislocation of the lens into the anterior chamber To exclude minor subluxation it is necessary to dilate the pupil maximally and perform a careful slit lamp examination Under these circumstances one sees in the severely affected person that the suspensory ligaments are redundant attenuated and fragmented

Myopia often of high grade is usually present a long orbit usually occurs as an integral part of the syndrome Spontaneous detachment of the retina is frequent

Cardiovascular System The principal cardiovascular manifestation of the Marfan syndrome *is a* weakness of the aortic media such that the portion subject to greatest hemodynamic stress of certain types—the ascending aorta—tends to undergo progressive dilatation or acute dissection The dilatation beginning as early as the first or as late as the fifth decade occurs first in the coronary sinuses Profound aortic regurgitation may precede evidence of dilatation of the aorta on ordinary radiographic study The clinical features of acute dissection are discussed on p 1338

Less common cardiovascular complications are bacterial endocarditis superimposed on minor

FIG 199 Composite chart relating manifestations of the Marfan syndrome to a single defect (*pedigree of causes*)

changes of the heart valves interatrial septal defect, and incomplete coarctation

Other internal ramifications include cystic disease of the lung and recurrent spontaneous pneumothorax

Differential Diagnosis Given cardiovascular and skeletal manifestations consistent with the Marfan syndrome one cannot be certain of the diagnosis unless ectopia lentis the most specific of the components of the syndrome can be demonstrated or unless close relatives display unmistakable evidence of the disease Confusion results from the fact that there is wide variability in the clinical severity of this syndrome and its individual components display some independence in their severity ("expressivity") or even in whether they are present at all (penetrance) When the mutant gene for this syndrome occurs in pyknic stock the affected person is likely to display less impressive skeletal abnormalities The patient must be judged against the background of his family

Intrauterine insults to the embryo such as maternal rubella can produce changes in the eye heart and skeleton (including arachnodactyly) which superficially suggest the Marfan syndrome

Inheritance The Marfan syndrome is usually inherited as an autosomal dominant

Pathology and Basic Defect The main histologic abnormality is that of the aortic media Probably normal at birth it undergoes changes which in the mildest form are identical with Erdheim s cystic medial necrosis seen in other settings In its advanced form there are loss of elastic fibers scarring hyperplasia of smooth muscle in large whorls and dilatation of the vasa vasorum What element of connective tissue is fundamentally defective is unknown The elastic fiber is under suspicion

THE EHLERS DANLOS SYNDROME

Definition The Ehlers Danlos syndrome (synonyms cutis hyperelastica India rubber men dermatorrhexis with dermatochalasis and arthrochalasis etc) is a heritable and generalized disorder of one element of connective tissue clinically manifested by fragility and hyperelasticity of the skin and loose jointedness

Clinical Manifestations Characteristically the skin can be stretched through an unusually great range yet returns promptly to its normal position on release (Fig 200) Later on the skin may lose its elasticity become truly *cutis laxa* and hang in flabby folds or wrinkles The skin is fragile so that minor trauma is likely to produce gaping fish mouth wounds which bleed little and hold sutures poorly There is easy bruisability Firm spherules up to about 1 cm in diameter develop subcutaneously can be moved about through a considerable range and can be demonstrated radiographically because of calcification Cigarette paper" scars develop over the knees shins etc So called molluscoid pseudotumors develop on the knees ankles and elbows as soft poorly outlined swellings that can be several centimeters in diameter

The loose jointedness results in genu recurvatum habitual dislocation of various joints flat feet etc Recurrent hydrarthrosis may result from the repeated trauma due to poor stabilization especially in the knees

Internal ramifications include diaphragmatic hernia or eventration of the diaphragm ectasia of portions of the gastrointestinal and respiratory tracts and spontaneous pneumothorax

Inheritance The Ehlers Danlos syndrome is usually inherited as an autosomal dominant

Pathology and Basic Defect The basic defect appears to be abnormality in the way the collagen "wickerwork is arranged such that excessive extensibility of collagenous structures is possible The normal elastic tissues appear to function in restoring structures to their normal position the elastic fibers may in fact be hyperplastic possibly in response to the repeated stimulus of extra stretching

OSTEOGENESIS IMPERFECTA

Definition Osteogenesis imperfecta (synonyms fragilitas ossium osteopsathyrosis idiopathica disease of Eddowes Lobstein van der Hoeve Vrolik etc) is a heritable generalized disorder of one element of connective tissue with clinical manifestations in the eye (blue sclerae) the ear (progressive deafness) the skeleton (especially multiple fractures see p 671) the joints (loose jointedness) and the skin The nosography of this syndrome has been much confused because of this wide variability in its clinical expression Osteogenesis imperfecta *congenita* and *tarda* have been separated A further separation of the tarda type into *levis* and *gravis* forms has been suggested A hereditary disease characterized by fragility of bones without blue sclerae has been claimed as a separate entity and called specifically *osteopsathyrosis idiopathica* Until there is convincing evidence to the contrary however the information available leads the writer to maintain that *all the several clinical pictures which have been described and which go by separate names in many instances are one and the same disease which has wide systemic ramifications and an exceedingly great range of clinical severity*

Clinical Manifestations *Skeleton* Multiple fractures with trivial trauma are a main feature (Fig 201) Intrauterine fractures may permit antenatal diagnosis Usually after puberty the victim of this disease becomes less subject to fractures susceptibility may return in later life especially after the

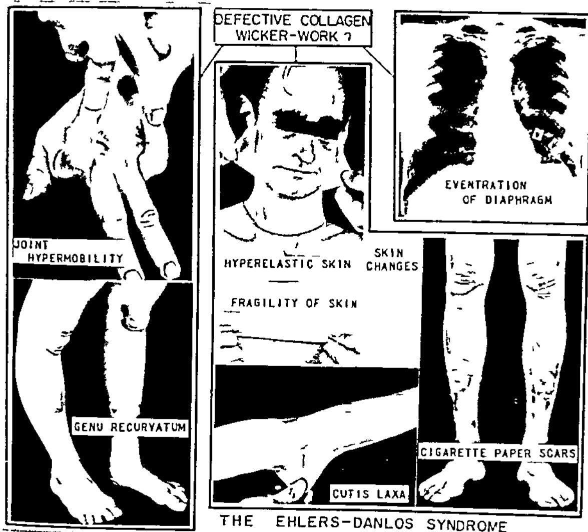

FIG 200 Pedigree of causes for the Ehlers Danlos syndrome

menopause in the female Bowing of bones porotic appearance by x ray without fracture "codfish" or "hourglass" vertebrae platybasia (basilar impression of the skull p 1543) are all features Dwarfism with short legs and relatively large head may be confused with achondroplasia The French artist Toulouse Lautrec is thought to have had osteogenesis imperfecta The calvarium tends to bulge laterally and the head and face have a triangular configuration which often permits diagnosis from photographs alone

Eye The change in the sclera which may be various shades of blue is the only important ocular feature

Ear The deafness has the clinical features of conventional otosclerosis variable age of onset steady progression, and likelihood to begin during pregnancy The tympanic membrane may be blue like the sclera

Joints Loose jointedness is one of the four cardinal features of the disease It is responsible at least in part, for flat feet kyphoscoliosis and habitual dislocation of joints Weakness of ligaments and tendons responsible for the loose-jointedness sometimes results in rupture of tendons from relatively minor stress

Others. Hernia is frequent The teeth are characteristically small misshapen and bluish yellow Kyphoscoliosis can lead in later life to cardiorespiratory complications

Inheritance Usually osteogenesis imperfecta is clearly inherited as an autosomal dominant. Some aspects of its genetics are still confused Certain features especially those concerning sporadic cases suggest a recessive mode of inheritance

Pathology and Basic Defect In the bones peculiar basophilic-staining material is found in place of osteoid In other tissues there is a sparsity of

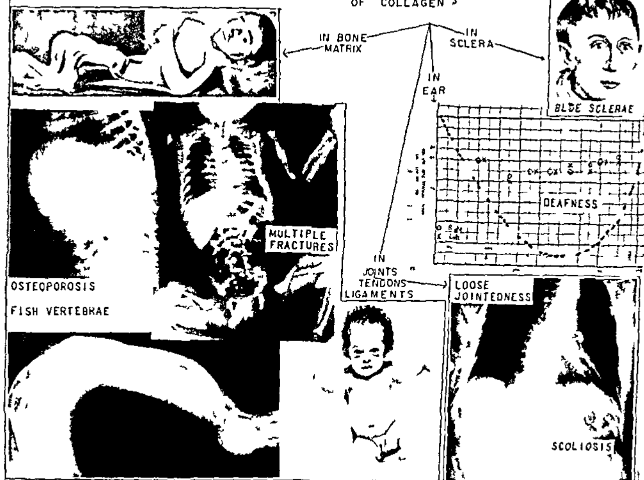

Fig 201 Pedigree of causes for osteogenesis imperfecta

collagen fibers and replacement by fibers with tinctorial and other characteristics of reticulin There appears to be a generalized defect in maturation of collagen

PSEUDOXANTHOMA ELASTICUM

Definition Pseudoxanthoma elasticum (synonyms PXE Groenblad Strandberg syndrome) is a hereditary generalized disorder of one element of connective tissue resulting in premature breakdown of the skin in exposed areas angioid streaks in the fundus oculi and hemorrhage from arterial degeneration

Clinical Manifestations *Skin* In the second third or fourth decade of life patients affected by PXE are likely to develop changes in the skin of the neck axillae inguinal areas and periumbilical zone consisting of thickening grooving and formation of yellowish diamond shaped rectangular and polygonal nodules (Fig 202) The skin in involved areas becomes inelastic lax and redundant In females the changes in the neck may be cosmetically disturbing

Eye Angioid streaks develop at a variable time often as early as the second decade They are brownish or gray and four or five times wider than the veins but resemble vessels in the manner in which they course over the fundus Proliferative changes occur in the retina with angioid streaks as points of origin Hemorrhage contributes further to the ocular damage which may progress to near blindness

Arterial Tree Weak or absent pulses may be found in the extremities Calcification of arteries is often demonstrable by radiography early in life Intermittent claudication and easy fatigability of the arms and legs occur Many of the affected persons suffer from angina pectoris and hypertension Recurrent gastrointestinal hemorrhage is the problem which most often brings the patient to the attention of the internist Occasionally some lesion such as peptic ulcer or hiatus hernia is discovered and the vascular disease of PXE is considered only

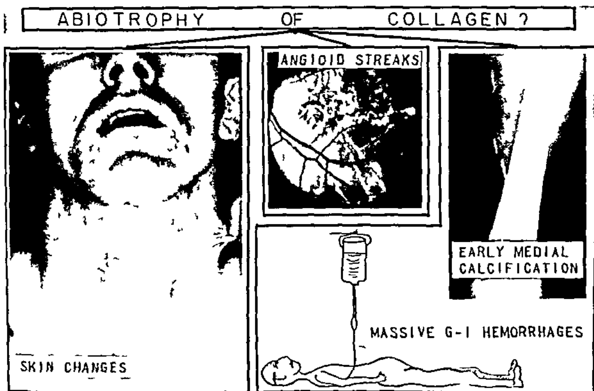

Fig 202 Pedigree of causes for pseudoxanthoma elasticum

an aggravating factor More often no such lesion *is found Hemorrhage from other sites—uterine* urinary nasal or subarachnoid—may occur

Inheritance Pseudoxanthoma elasticum behaves genetically like an autosomal recessive

Pathology and Basic Defect The skin and media of arteries of intermediate and smaller size (and occasionally the endocardium and pericardium) become the site of markedly altered connective tissue fibers which are basophilic have an affinity for calcium and display the tinctorial characteristics of elastic fibers In some areas material of this description is reduced to amorphous or granular accumulations The basis for angioid streaks appears to be basophilic change and subsequent crazing (cracking) of Bruck s membrane behind the retina A growing body of evidence suggests that fundamentally PXE is a hereditary weakness of collagen fibers (not elastic fibers) which renders them prone to undergo what some call elastotic degeneration under stress

THE HURLER SYNDROME

Definition The Hurler syndrome (synonyms gargoylism Hunter Hurler Pfaundler syndrome lipochondrodystrophy dysostosis multiplex, etc) is thought to be a generalized heritable disorder of one element of connective tissue manifested by a characteristic malformation of the skeleton stiff *joints deafness lesions of the* arterial retina and heart valves hepatosplenomegaly corneal clouding and impairment of intellect (Fig 203)

Clinical Manifestations Although previously considered the exclusive property of the pediatrician this syndrome is coming more to the attention of the internist Milder forms of the disease are consistent with survival to adulthood and improved supportive measures permit longer survival of more severely affected cases The child is often considered normal at birth with time the abnormality in pattern of growth of the skeleton becomes evident and slowing of intellectual development, deafness enlargement of the liver and spleen and clouding of the cornea set in The deformity of the facial bones results in stertorous respiration frequent upper respiratory infection and mouth breathing which creates an appearance superficially suggesting cretinism Virtually all joints of the body display reduced mobility Dyspnea precordial pain and congestive heart failure develop Murmurs referable to any of the four valves of the heart can develop The mitral and aortic valves are most often affected Sudden death seemingly cardiac in origin is frequent Intercurrent respiratory infection is also a common cause of death

Inheritance There are probably two genetic variants of this disease—one inherited as an autosomal

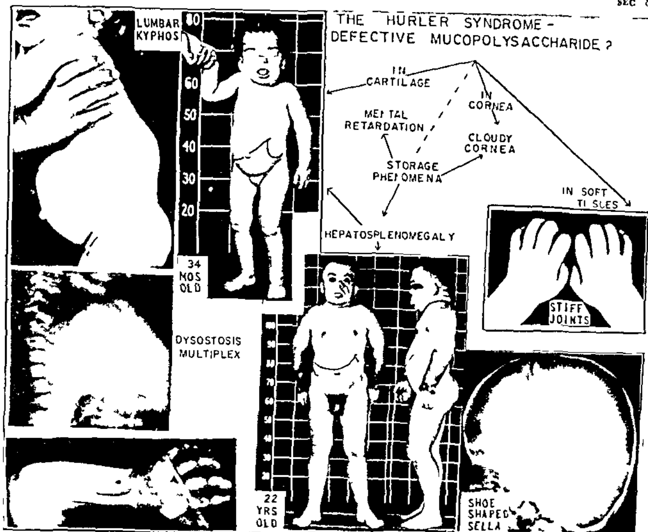

Fig 203 Pedigree of causes for the Hurler syndrome

recessive and one as a sex linked recessive like hemophilia In the variety with sex linked inheritance the cornea is less likely to be affected intellect is less severely impaired gibbus (or lumbar kyphosis) is less frequent and survival to a later age even the forties is possible Otherwise the clinical features of the two varieties are identical

Pathology and Basic Defect Cartilage fascia tendons periosteum blood vessels heart valves meninges and cornea show characteristic cells which are thought to arise from fibroblasts these are distended by a substance with properties of a polysaccharide and have been designated as gargoyle cells Material presumably identical with that in the fibroblasts balloons the nerve cells of the central nervous system peripheral ganglions and retina the Kupffer and parenchymal cells of the liver the reticulum cells of spleen and lymph nodes and the epithelial cells of endocrine glands Extensive deposits may be found in the intima of coronary arteries aorta and pulmonary artery The heart valves become scarred and deformed The polysaccharide nature of the intracellular deposits has been confirmed in all tissues except the brain where some consider the material to be phospholipid

The basic defect is thought to concern either mucopolysaccharide or *structural polysaccharide* the latter term referring to a component of cellular structure

262 COLLAGEN DISORDERS

B V Jager

The term *diffuse collagen disorders* is applied to a group of diseases in which extensive involvement of connective tissue appears to be the salient fea

ture Rheumatoid arthritis rheumatic fever poly arteritis nodosa systemic lupus erythematosus diffuse scleroderma (progressive systemic sclerosis) and dermatomyositis usually are placed in this category Both clinical and pathologic considerations make it appropriate to include serum sickness here In addition many observers include other disorders such as allergic purpuras (p 1203) certain cases of Loeffler's syndrome (p 1397) thromboangiitis obliterans (p 1341) and subacute bacterial endocarditis (p 970)

Certain of the diseases enumerated above are considered elsewhere in this book This and the following chapter concern *serum sickness polyarteritis nodosa systemic lupus erythematosus diffuse scleroderma dermatomyositis* and *polymyositis* Also mention is given to *scleredema adultorum* because of its clinical similarity to scleroderma *Cranial arteritis* and *Wegener's granulomatosis* both unusual are considered briefly The main characteristics of *Weber Christian disease* also are presented although it is recognized that this disease differs significantly from the others

Pathologically the four diseases polyarteritis nodosa systemic lupus erythematosus diffuse scleroderma and dermatomyositis have many features in common In each there may be proliferative and degenerative changes in connective tissue Most familiar is the so-called fibrinoid" degeneration in which collagenous connective tissue assumes the tinctorial characteristics of fibrin It is not known what gives rise to this fibrinoid substance Arteritis or vasculitis may be found in all of these diseases thus is least frequent in dermatomyositis

Clinically also there are many similarities Raynaud's phenomenon may occur in any one of them Retina lesions are observed in certain cases with each disease Except in dermatomyositis arthralgia and arthritis are frequent Erythematous and purpuric skin lesions may be observed in any of the four Visceral lesions especially in the heart lungs and kidney are encountered in these disorders again being least common in dermatomyositis Systemic lupus erythematosus stands clearly apart from the others in this condition alone is there a plasma or serum factor capable of producing the so-called L E cell

The etiology of none of these diseases is known It is tempting to assume that they all represent a particular type of allergic response This is all the more alluring since serum sickness disease induced in rabbits reproduces many of the pathologic characteristics of polyarteritis nodosa rheumatic fever and glomerulonephritis However definitive proof that allergy is responsible for these four clinical entities is lacking

A comparison of the symptomatology of the four diseases is shown in Table 133 p 1700 The tabulation of frequency of symptoms is arbitrary and is intended as a guide to the likelihood of a given symptom in the well-developed stage of the disease but not necessarily in the initial or terminal phase

SERUM SICKNESS

Serum sickness is a delayed systemic reaction resulting from administration of foreign serum or certain drugs to susceptible individuals The usual clinical manifestations include fever skin eruptions arthralgia edema and lymphadenopathy

Serum sickness was recognized when large amounts of whole horse serum were introduced into man for the prophylaxis and treatment of diphtheria Not only whole horse serum but also refined globulin fractions containing antitoxin to diphtheria and tetanus toxins may give rise to serum sickness as does bovine albumin which was tested in man as a plasma substitute In addition sensitivity to a number of drugs including sulfonamides penicillin and iodides may produce the same symptom complex

The production of serum sickness in experimental animals has evoked considerable interest. After a single large parenteral injection of whole horse serum bovine albumin or bovine globulin relatively few symptoms are noted in the rabbit When animals are sacrificed at intervals after the administration of serum however histologic examination often shows lesions similar to those of polyarteritis nodosa rheumatic fever and glomerulonephritis in man The acute lesions occur at the time when the administered antigen (heterologous serum) is being rapidly removed from the plasma. Usually healing of lesions is in progress by the time that antibody to the injected protein is demonstrable in the serum Administration of ACTH or cortisone to the rabbit following injection of the foreign serum protein reduces the incidence of lesions

Serum sickness in man usually is a brief disease with an abrupt onset 3 to 21 days after administration of a serum product or a drug Most reactions begin from the fourth to the tenth day Early in the illness there is fever with arthralgia and myalgia of variable severity Occasionally there is swelling of the joints An urticarial eruption occurs as does a feeling of soreness of the throat. The lymph nodes become enlarged and the spleen may become palpable Later erythematous and sometimes purpuric skin rashes are to be seen Cardiac arrhythmias are encountered and rarely there is pericarditis There may be diarrhea which sometimes is hemorrhagic Anuria or oliguria may appear but seldom persists longer than a few days A variety of neurologic disturbances have been noted in serum sick

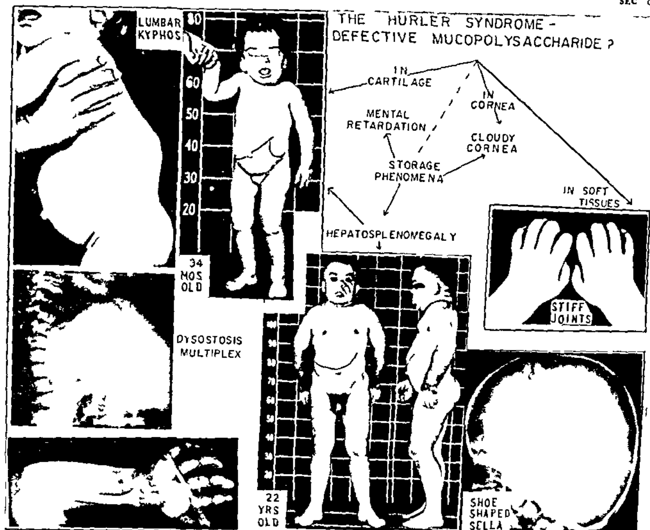

Fig 203 Pedigree of causes for the Hurler syndrome

recessive and one as a sex linked recessive like hemophilia In the variety with sex linked inheritance the cornea is less likely to be affected intellect is less severely impaired gibbus (or lumbar kyphosis) is less frequent and survival to a later age even the forties is possible Otherwise the clinical features of the two varieties are identical

Pathology and Basic Defect Cartilage fascia tendons periosteum blood vessels heart valves meninges and cornea show characteristic cells which are thought to arise from fibroblasts these are distended by a substance with properties of a polysaccharide and have been designated as gargoyle cells Material presumably identical with that in the fibroblasts "balloons the nerve cells of the central nervous system peripheral ganglions and retina the Kupffer and parenchymal cells of the liver the reticulum cells of spleen and lymph nodes and the epithelial cells of endocrine glands Extensive deposits may be found in the intima of coronary arteries aorta and pulmonary artery The heart valves become scarred and deformed The polysaccharide nature of the intracellular deposits has been confirmed in all tissues except the brain where some consider the material to be phospholipid

The basic defect is thought to concern either mucopolysaccharide or *structural polysaccharide* the latter term referring to a component of cellular structure

262 COLLAGEN DISORDERS

B V Jager

The term *diffuse collagen disorders* is applied to a group of diseases in which extensive involvement of connective tissue appears to be the salient fea

tively small number of cases obvious hypersensitivity to serum or to a drug initiates the process In others symptoms appear during convalescence from an infection much as acute rheumatic fever follows streptococcal pharyngitis In most cases however no predisposing factor is apparent Bronchial asthma cutaneous eruptions severe abdominal pain cardiac failure glomerulonephritis arthralgia or arthritis myalgia and peripheral neuritis are only a few of the presenting symptoms or findings which may be observed

As the disease progresses almost any region of the body may be affected Frequently it is the multiplicity of superficial and visceral lesions which first suggests the diagnosis A variety of cutaneous eruptions may be observed Purpura erythema nodosum erythema multiforme and focal necroses suggesting embolic manifestations may be encountered There may be subcutaneous nodules Many patients present themselves primarily for neurologic disorders Subjective paresthesias sensory impairment muscle tenderness and muscle wasting suggest the presence of peripheral neuritis Headaches convulsions papilledema and cranial nerve palsies may be confused with cranial neoplasms Muscle tenderness may appear even in the absence of peripheral neuritis Painful joints which may or may not be swollen and tender are observed often In some instances deformities of joints that resemble changes in rheumatoid arthritis are found Retinal hemorrhages and exudates are frequent

The cardiovascular system frequently is implicated At least half the patients develop hypertension during the illness Pericardial friction rubs cardiac enlargement and tachycardia out of proportion to existent fever or anemia may call attention to heart injury Systolic murmurs are noted frequently but diastolic murmurs are unusual unless there has been previous acute rheumatism Electrocardiographic abnormalities are not unusual A few patients develop cold hypersensitivity of the Raynaud type

A number of patients develop asthma and less frequently cough hemoptysis pulmonary infiltrations or pleurisy

Involvement of the gastrointestinal tract may be signalized by nausea vomiting diarrhea or melena Perforation of the intestine or gallbladder has been observed The character of the abdominal pain may suggest a surgical emergency such as infarction of bowel acute appendicitis or acute cholecystitis Indeed these conditions may be present at operation and only after histologic examination is it possible to recognize the disease as polyarteritis nodosa Polyarteritis is a common cause of true infarction of the liver

Renal injury is observed in a relatively large proportion of cases There may be gross hematuria more often other symptoms and signs of impaired renal function are observed and they can progress to uremia Hypertension usually is present when renal damage is marked

During the course of the disease intermittent fever is usual The height and type of the fever vary Loss of weight and of strength often are striking

Death results most often from renal injury with concomitant hypertension or from heart failure secondary to extensive myocardial damage A variety of other visceral lesions may lead to death however

Laboratory Data Moderate normocytic anemia is a common finding Characteristically the leukocyte count is elevated ranging from 12 000 to 50 000 per cubic millimeter Very occasionally there is leukopenia The differential count usually discloses an increase in polymorphonuclear leukocytes In about one fifth of the cases a marked eosinophilia is observed in a random examination When repeated differential counts are made eosinophilia often transient is found in a greater proportion of cases The urine may contain albumin casts erythrocytes and white blood cells Spinal fluid is usually normal even when there is peripheral neuritis In the serum slight hypoalbuminemia and moderate hyperglobulinemia are common findings

Diagnosis It usually is not possible to establish a diagnosis of polyarteritis nodosa in the absence of histologic evidence of arteritis Clinically the changing clinical picture with evidence of involvement of many tissues or organs and the remittent course are suggestive as are leukocytosis eosinophilia and urinary abnormalities The correct diagnosis is established in approximately one third of cases during life

When the disease is suspected biopsies should be made of skin subcutaneous tissue and muscle If the biopsy and the clinical picture are compatible the diagnosis of polyarteritis nodosa is justified Caution should be exercised in the acceptance of this diagnosis on a report of histologic changes alone The cutaneous lesions of erythema multiforme erythema nodosum Weber Christian disease and nodular vasculitis may show similar vascular abnormalities In addition one finds that similar lesions occur in rheumatoid arthritis and systemic lupus erythematosus and less frequently in diffuse scleroderma and dermatomyositis Moreover patients with drug sensitivity and with serum sickness may show the lesions of polyarteritis nodosa It is debatable whether or not such patients should be given a diagnosis of this disease These drug and serum sensitivity vascular lesions often seem to be transient and full clinical recovery is frequent By

ness Most common is a unilateral radiculitis or neuritis affecting particularly muscles in the shoulder girdle Infrequently there is a polyneuritis or a meningoencephalitis

Laboratory findings are relatively few There often is a moderate leukocytosis The differential count early in the disease may reveal considerable numbers of plasma cells There is no eosinophilia with the illness produced by foreign serums although it may be found with the illness induced by drugs As in rabbits antibodies to the foreign serum appear late in the disease The urine may contain protein leukocytes erythrocytes and casts Electrocardiograms may reveal conduction defects or arrhythmias

Serum sickness rarely lasts more than several weeks Epinephrine injections or antihistaminics produce prompt disappearance of urticaria Acetyl salicylic acid or sodium salicylate usually is helpful in controlling the discomfort of arthralgia and myalgia For severe symptoms short courses of ACTH or cortisone and related steroids are effective

Serum sickness usually is benign and full recovery is to be expected A few patients have died from serum sickness from the drug induced sickness which resembles it or from the disease for which the agent was given Upon histologic examination the tissues of these individuals have sometimes shown an arteritis indistinguishable from that observed in polyarteritis nodosa

POLYARTERITIS NODOSA

Definition This is a systemic disease chronic or subacute in its course and frequently fatal characterized by damage to arterioles and medium sized arteries The distribution of the vascular lesions varies with resulting diversity of visceral involvement and a broad spectrum of clinical manifestations

Synonyms or allied afflictions include periarteritis nodosa disseminated necrotizing vasculitis generalized arteritis and necrotizing angiitis

Etiology In experimental animals histologic lesions of necrotizing arteritis similar to those seen in human cases of polyarteritis can be produced by such diverse means as sensitization to foreign proteins induction of hypertension or administration of desoxycorticosterone acetate In some patients with polyarteritis nodosa sensitization to heterologous serum or to drugs such as sulfonamides iodides and penicillin clearly seems to have produced the disease In the majority of cases however there is no obvious evidence of sensitization Efforts have been made to separate the clinical cases of polyarteritis into various groups For example the *hypersensitivity* type is said to have a short course the lesions all appear of the same age histologically and the pulmonary vessels are frequently affected In a second type the course is prolonged and intermittent and pulmonary vessels are spared A third type has been observed to occur terminally in patients who have had marked hypertension either essential or secondary to renal disease Such separation suggests a varied etiology for the human disease polyarteritis nodosa However, it is not usually possible to classify the disease in a given patient on clinical grounds or by post mortem studies

Incidence The ages of affected individuals have ranged from three months to seventy eight years but the highest incidence is between forty and sixty years of age The ratio of affected males to females is variously stated as 3 1 or 4 1

Pathology This disease primarily affects medium sized and small arteries and arterioles Large arteries may be involved through lesions of the vasa vasorum Rarely veins are affected Gross anatomic findings are variable Small aneurysms may be noted in mesenteric arteries or in arteries elsewhere More often one detects only visceral lesions resulting from ischemia or hemorrhage Lymph node enlargement splenomegaly and serous effusions occur occasionally

Histologically the characteristic changes are found in small and medium sized arteries and in arterioles Often only short segments of a vessel are affected The entire circumference of the vessel or only a portion of it may be involved The distribution of vascular alterations from case to case varies considerably In approximately decreasing frequency lesions of vessels are observed in the kidney heart liver gastrointestinal tract mesenteric vessels spleen pancreas lung muscles and peripheral nerves Almost any organ and tissue of the body may be affected

The fundamental abnormality consists of necrosis and fibrinoid change of the vessel wall with accompanying leukocytic infiltration Thrombosis of the injured vessel may result or an aneurysm may develop With healing fibrosis appears and may lead to narrowing or obliteration of the lumen In autopsy studies it is often possible to demonstrate vessels in all stages of degeneration and repair This is in keeping with the remittent clinical pattern so frequently observed

Clinical Manifestations The symptomatology of this disorder is as diversified as that of syphilis but unfortunately it is not detectable by any serologic test Only by histologic examination of material obtained by biopsy or necropsy can a positive diagnosis be made

The onset may be insidious or abrupt In a rela

ened glomerular tuft basement membrane ("wire loop lesion) periarterial fibrosis in the spleen (onionskin lesion) focal necrosis of lymph nodes and hematoxylin bodies (amorphous globules of desoxyribonucleic acid) situated in various tissues such as the heart kidney or lymph nodes

Clinical Manifestations Like the pathologic changes the clinical manifestations of this disorder are extremely varied This has become more evident since the development of the L E cell test which is regarded as specific for systemic lupus erythematosus The presenting clinical picture may be *hemolytic anemia* or *thrombocytopenic purpura* Frequent early symptoms are fever arthralgia and arthritis pleuritic pain loss of weight dyspnea and orthopnea The skin eruption formerly regarded as almost essential for the diagnosis can precede systemic symptoms for years It may appear early or late in the illness and may be transient As the disease progresses constitutional symptoms such as fever tachycardia anorexia and loss of weight become severe Remission of all symptoms may ensue and persist for long periods Frequently with exacerbations symptoms become increasingly severe and additional organs tend to become affected Usually the outcome is fatal however the course of this disease extends over 5 to 15 years in many instances

The characteristic skin lesion is an erythematous eruption over the malar region and the bridge of the nose—the butterfly distribution The lesions are raised and indurated Long standing lesions tend to have sharp margins and may show silvery scales which when scraped away reveal dilated follicles When the typical rash of lupus erythematosus is present and when there are no apparent constitutional symptoms the term *discoid lupus erythematosus is applied Although it has been thought that* it is rare for discoid lupus to become a systemic disorder careful studies of patients with discoid lupus erythematosus indicate that previously unsuspected clinical and laboratory abnormalities are often present

The Senear Usher syndrome is regarded as a variant of systemic lupus erythematosus In this disorder erythematous scaly lesions of the face and neck are found in conjunction with bullous lesions over the rest of the body The eruptions apart from those on the face simulate pemphigus vulgaris

In addition many other skin changes may be encountered including telangiectasia pigmentation (focal or diffuse) purpura ecchymoses indurated nodules in the finger tips urticaria erythema multiforme or nodosum and patchy or total alopecia Infrequently papular and ulcerated lesions are observed in the mouth

Nearly all patients develop joint symptoms There may be only a migratory arthralgia Frequently there are tenderness and swelling of several joints A number of patients show deformities of joints which cannot be distinguished from rheumatoid arthritis

Edema is another common finding This may be periorbital dependent diffuse or focal in character

Pleuritic pain frequently develops and may be associated with a friction rub or an effusion Pericardial rubs and effusions also may be observed In some patients roentgenograms of the chest disclose patchy atelectasis of the lower lobes of the lungs with an elevated diaphragm In addition there may be chronic pulmonary infiltrations of varying extent Patients with systemic lupus erythematosus appear to be predisposed to bacterial pulmonary infections It may be difficult or impossible to differentiate primary lupus pneumonias from those due to infectious agents

The cardiovascular system shares in the stigmas of systemic lupus erythematosus Apart from pericardial changes there may be myocardial damage with resultant dilatation of the heart and cardiac insufficiency Systolic murmurs are frequent Hypertension of significant degree occurs in less than 20 per cent of cases Even patients with markedly impaired renal function often are normotensive This feature may be useful in differentiating this disorder from other types of chronic renal disease where hypertension is to be expected A few patients give a history of hypersensitivity of the fingers to cold usually of the Raynaud type This type of vasomotor disturbance may appear long before other manifestations

There is no pathognomonic retinal lesion in this disorder Hemorrhages exudates or cytoid bodies are found in about one fourth of patients who are *observed for long periods Abdominal pain is intense* and prolonged in some patients There may be diarrhea and occasionally melena The liver often is moderately enlarged Jaundice is rare except in the few individuals who have a hemolytic anemia Splenomegaly is noted in about one fifth of the cases

In two thirds of the cases studied for long periods the urine contains protein and granular casts Frequently the urine becomes normal during remissions A few patients have massive proteinuria which may be associated with the other findings of the nephrotic syndrome Approximately 10 per cent of all cases progress to renal insufficiency

Regional or diffuse lymph node enlargement is present in approximately one third of the patients The cervical chain of nodes is particularly prone to enlargement in this disease

There is growing evidence that the central nervous system is implicated frequently Transient cerebrospinal pleocytosis with headache and stiff

Table 133 COMPARISON OF THE CLINICAL CHARACTERISTICS OF POLYARTERITIS NODOSA, SYSTEMIC LUPUS ERYTHEMATOSUS, SCLERODERMA, AND DERMATOMYOSITIS*

Clinical characteristics	Polyarteritis *nodosa*	Systemic lupus *erythematosus*	Diffuse *scleroderma*	Dermatomyositis
Sex incidence M F	4 1	1 4	2 1	1 1

Abnormal urinary sediment	++	+++	+	±
L E cells	−	+++	−	−

* Frequency roughly estimated as follows +++ = 60–100% ++ = 40 59% + = 20–39% ± = less than 20% − = no greater than in the ordinary population of the same age

contrast the vascular lesions in the many cases of polyarteritis are recurrent and chronic progressive illness is the sequence

Therapy Spontaneous remissions are encountered frequently in this disease In severely ill patients without serious renal damage the use of ACTH or cortisone and related steroids may produce good relief of symptoms but these drugs can aggravate *renal insufficiency in individuals* with already damaged kidneys

SYSTEMIC LUPUS ERYTHEMATOSUS

Definition *Systemic lupus erythematosus usually* is a chronic disorder in which there are remissions and exacerbations The clinical findings are variable In a typical instance there may be intermittent fever arthralgia or arthritis a characteristic skin eruption proteinuria leukopenia hyperglobulinemia and a positive test for L E cells Certain variants of this disorder have been termed *Libman Sacks disease* (atypical verrucose endocarditis) and the *Senear Usher syndrome*

Incidence About 80 to 85 per cent of reported cases have occurred in females The disease may appear at any age but is most commonly seen between the ages of fifteen and forty years

Etiology The cause is not known Frequently the earliest symptoms follow intense exposure to sunlight In other instances infections and trauma of various sorts appear to initiate the process A few patients who have received 1 hydrazinophthalazine (hydralazine Apresoline) for control of hypertension *develop an illness resembling acute rheumatoid* arthritis When the medication is continued some of these individuals show skin eruptions polyserositis fever anemia proteinuria and positive tests for L E cells It is not claimed that this syndrome is identical with the disease systemic lupus erythematosus Nonetheless the similarity of the two conditions is striking

Pathology In autopsied cases gross findings *often are slight and may be absent The serous* membranes (pleura pericardium peritoneum joints) may exhibit thickening with or without effusions Moderate splenomegaly and focal or dif*fuse lymph node enlargement occur* Small and large verrucose nonbacterial endocardial lesions involving the heart valves and adjacent mural endocardium are found in approximately 30 per cent of cases Frequently the anatomic changes are complicated by terminal bacterial infections

Histologically connective tissues show fibrinoid changes and leukocytic infiltrates Hemorrhage may be observed about capillaries arterioles may be thickened and narrow*ed or contain thrombi It is* said that typical skin lesions present a characteristic microscopic appearance Other features are thick

gradually withdrawn until another acute episode occurs In some individuals it is necessary to maintain constant treatment with ACTH or with cortisonelike drugs A gel of ACTH may be given once daily as an intramuscular injection It is estimated that a dosage of 100 mg daily of this substance will provide maximal adrenal stimulation After a satisfactory clinical response is achieved the dosage may be gradually decreased so long as it suffices to prevent serious symptoms Initially cortisone acetate usually is administered orally at 8 hr intervals in a total of 200 to 300 mg per 24 hr Potassium chloride (8 to 12 Gm daily) and a low salt diet should be prescribed Often it is possible to reduce the daily dosage of cortisone to a maintenance level of 50 to 100 mg Instead of cortisone acetate one may use an oral preparation of hydrocortisone Here the dosage is approximately 80 per cent the amount of cortisone Prednisone and prednisolone although more expensive than cortisone are effective in a dosage of 20 to 25 mg per day given in three doses It may be necessary to use five to ten times these doses of steroids initially to achieve a response In particular the acute hemolytic anemia seen in this disorder seems unresponsive until large quantities of cortisone or related drugs are given

For less severe symptoms aspirin often will keep the patient comfortable

It is also possible to use quinacrine (Atabrine) This drug is useful in simple discoid lupus erythematosus and may be helpful in those with the systemic form of the disease It is recommended that the initial dose be 100 mg three times a day after meals If no response occurs and if no toxicity supervenes the dose can be increased to a maximal daily dose of 600 mg

General supportive measures are indicated Patients should avoid exposure to sunlight

SCLERODERMA

Definition Scleroderma is a disease characterized pathologically by an alteration in collagen tissue and clinically by focal or diffuse induration of the skin Fibrosis in visceral structures is frequent There may or may not be associated vasomotor disturbances and endocrine disorders The term *progressive systemic sclerosis* has been suggested for the disease but has not achieved wide usage

The etiology is unknown Endocrine vasomotor or neurotrophic factors and hypersensitivity have been suggested Diffuse scleroderma is a relatively uncommon disease which usually occurs between the ages of thirty and fifty years It is slightly more frequent in women

Pathology In the skin there is atrophy of the epidermis flattening of the dermal papillae atrophy of the dermal appendages and fragmentation of elastic tissue in the corium The corium appears more dense than usual because of swelling proliferation and fusion of collagen fibers which occasionally show fibrinoid degeneration Small arteries in the corium are thickened and narrowed Early there may be edema and a moderate mononuclear cell infiltration Increases in collagen tissue may be present in muscle fascia in muscle itself and in various viscera especially the heart and lungs In the esophagus stomach and intestine there are atrophy of smooth muscle and fibrosis of the submucosa Ulceration of the lower esophagus is not unusual Occasionally the kidneys show a peculiar lesion in which marked intimal thickening occurs in interlobular arteries leading to ischemic necrosis of the renal cortex

The disease exists in a focal form in which are found indurated cutaneous lesions which tend to follow the distribution of peripheral nerves This disorder known as *morphea* or *scleroderma circumscripta* is rarely associated with the more diffuse form of the disease and rarely presages its development Diffuse scleroderma varies in site of onset and in extent Not infrequently the earliest and most extensive skin changes are to be found on the hands forearms and face In other patients the neck trunk and proximal portions of the arms may be principally affected

Clinical Manifestations The onset often is insidious Early symptoms include slight fever edema which may be diffuse or focal arthralgia and mild arthritis Many patients give a history of vasomotor disturbances particularly of the Raynaud type for months or years preceding the changes in the skin

As the disease progresses conspicuous changes are found in the skin especially of the face neck and upper extremities The severity of the process in different parts of the body may vary greatly The involved skin has a waxy sheen is taut feels thickened and cannot be lifted from the underlying structures In the affected areas pigmentation depigmentation loss of hair or telangiectasia are often noted Occasionally there may be cyanosis and erythema When the face is involved the features assume a masklike appearance and there may be limitation of the movements of the jaw Induration of the skin of the extremities and girdle regions may give rise to limited motion and contractures Clubbing and other deformities of the fingernails may be observed Trophic ulcerations may develop in any involved area especially on the finger tips Paresthesias and reduction in sensory perception may be present Indurated lesions may be found on the tongue and gums

The muscles may display induration and atrophy In some instances they are also tender usually the result of an associated polymyositis In a few pa

neck occurs during the course of the disease in many patients Epileptiform seizures may appear early or late in the illness The psychoses and confusion noted in some patients are thought to be ascribable to an organic brain syndrome resulting from multiple small infarcts of the cerebral hemispheres Particularly in the late stages of the disease one encounters neurologic damage evidenced by gross tremors or hemiplegia Electroencephalograms often are abnormal in systemic lupus erythematosus Polyneuritis is present in less than 2 per cent of the cases

Laboratory Data Examination of the blood usually reveals a normochromic anemia Occasionally there is an acute hemolytic anemia Cold agglutinins positive direct Coombs tests and less frequently positive indirect Coombs tests are encountered *with or without hemolytic anemia* The leukocyte count is low (2 000 to 4 000 per cubic millimeter) but may be normal or elevated Differential counts in some instances reveal a relative lymphopenia with a preponderance of neutrophils An increase in the number of eosinophils is rare There may be extreme thrombocytopenia In some patients a circulating anticoagulant has been found often in conjunction with a bleeding tendency

The erythrocyte sedimentation rate is elevated The total serum protein usually is normal but serum albumin is decreased and globulin is increased Electrophoretic studies have disclosed the hyperglobulinemia to be due to an increase in both alpha and gamma globulin When the serum of a patient with this disease is chilled there often is a small amount of protein precipitated so called cryoglobulin (p 1229)

False positive flocculation tests (Hinton Kahn Eagle VDRL) and false positive complement fixation tests (Wassermann) or anticomplementary Wassermann tests are found in nearly one fourth of the cases and can precede the onset of clinical manifestations by many years

It is usual to find red cells white cells and hyaline and granular casts in the urine The demonstration of L E cells establishes the diagnosis of systemic lupus erythematosus When leukocyte or bone marrow suspensions from the patient or from a normal subject are allowed to incubate with plasma or serum from a patient with systemic lupus erythematosus there appear characteristic L E cells in the stained cellular sediment The L E cell is a large polymorphonuclear leukocyte containing an intracellular mass which has the shape but not the staining characteristics of a cell nucleus It has been demonstrated that this homogeneous mass contains depolymerized desoxyribonucleic acid indicating its nuclear origin In the sediment one may also see *tart* cells (histiocytes or polymorphonuclear leukocytes containing a mass identifiable as nuclear material) Other abnormalities include *rosettes* (clusters of granulocytes about a homogeneous mass) and *globs* (free masses of homogeneous material like that seen in the L E cell and identical with the hematoxylin bodies seen in histologic sections from patients with systemic lupus erythematosus) Only the L E cell can be regarded as specific in the diagnosis of systemic lupus erythematosus The exact mechanism for production of the L E cell is not known The plasma or serum factor is present in the gamma globulin fraction of the plasma of patients with this disorder False positive tests for L E cells have been observed to occur in a few patients who have been maintained for long periods on hydralazine (Apresoline) and who have an illness resembling systemic lupus erythematosus In addition positive tests have been obtained with *a few patients with acute sensitivity reactions to* penicillin There is no certainty as to the best procedure for inducing the L E cell phenomenon in vitro It is recognized that patients with this disease may have no demonstrable L E cells When repeated preparations for L E cells are performed in a uniform fashion in a given patient throughout his illness L E cells may decrease or rarely disappear during remissions of the disease that have occurred spontaneously or have been induced by therapy

Diagnosis It is now recognized that systemic lupus erythematosus is not a rare disease Especially in a female the presence of arthritis arthralgia fever or chest pain should suggest its possibility An accompanying typical facial rash will establish the diagnosis Anemia leukopenia slight albuminuria and an abnormal urinary sediment are helpful aids In the absence of possible drug or serum sensitization the diagnosis would be established by demonstrating the presence of L E cells Repeated tests should be made before stopping the search for L E cells In a few instances the diagnosis has been made by finding periarterial fibrosis in a spleen removed from a patient with thrombocytopenic purpura or by the finding of "wire loop" lesions in a needle aspiration biopsy of a kidney Systemic lupus erythematosus resembles many other diseases In particular acute rheumatic fever rheumatoid arthritis subacute bacterial endocarditis glomerulonephritis hemolytic anemia thrombocytopenia and chronic infections such as tuberculosis may simulate this disease

Treatment ACTH and cortisone or related steroids constitute the most effective therapy for this disorder The dosage needed varies with the severity of symptoms and with the type of disturbance that is predominant It has been emphasized that systemic lupus erythematosus is usually a remittent disease Often therapy may be employed only during an acute exacerbation and then be

vesicular and desquamative lesions have also been described Particularly in those patients in whom there is a history of Raynaud s phenomenon there may be sclerodermatous involvement of the fingers hands forearms and face

Edema or erythema of the face trunk or extremities is not infrequent Periorbital edema occurs in many patients The skin about the eyes may have a light purple (heliotrope) hue

Most characteristic is the evidence of muscle involvement Frequently the patients complain of stiffness tenderness decreased strength and easy fatigability of the affected muscles As the disease progresses skeletal muscles of the trunk and proximal portions of the extremities tend to show the greatest involvement Usually one can elicit tenderness by pressure and passive motion Atrophy contractures and calcification may be present

The striated muscles of the eyes pharynx, larynx the diaphragm or the intercostal muscles can be affected giving rise to diplopia dysphagia, hoarseness dyspnea Tachycardia and arrhythmias are the usual findings when the heart is affected Congestive heart failure is rare

In occasional cases one may encounter other manifestations such as tongue and mucous membrane lesions retinal changes lymph node enlargement splenomegaly hemorrhagic tendencies and arthralgia

Patients with dermatomyositis frequently lose weight However other constitutional symptoms are slight Fever is present in fewer than half the patients usually is low grade and tends to be intermittent

A number of patients with dermatomyositis are found to have concomitant malignant tumors Often the symptoms of malignancy are the first to appear The possibility of some type of malignant disease should be considered in every patient with dermatomyositis

Laboratory Findings Slight anemia is frequent The leukocyte count is usually normal In about 50 per cent of patients an increase in eosinophils or monocytes is found in the differential count Often the erythrocyte sedimentation rate is moderately increased There may be a reduction in serum albumin and an increase in serum globulin Proteinuria has been observed but other evidence of renal damage is uncommon

A relatively constant finding in adults is the reduction in the amount of urinary excretion of creatinine per 24 hr in association with a spontaneous creatinuria which may range from 200 to 1 200 mg per 24 hr Moderate daily fluctuations in creatinine excretion occur and variations may be found as the disease alters in severity

The histologic changes in biopsies of affected muscles are almost pathognomonic Occasionally similar changes are observed in the muscles of patients with diffuse scleroderma or systemic lupus erythematosus

Diagnosis The presence of muscle tenderness and muscle atrophy in conjunction with periorbital edema should suggest the diagnosis Helpful laboratory findings are decreased urinary creatinine excretion together with spontaneous creatinuria an increase in monocytes and eosinophils in the stained blood smear and biopsy evidence of muscle lesions

Early psychoneurosis may be suspected As the disease progresses the possibilities include polyarteritis nodosa systemic lupus erythematosus thyrotoxic myopathy peripheral neuritis progressive muscular atrophy myasthenia gravis myositis ossificans trichinosis sarcoidosis pellagra thromboangiitis obliterans and Addison s disease It may be difficult or impossible to differentiate between dermatomyositis and scleroderma until extensive muscle involvement is present A number of observers consider these two disorders to be variants of a single process

Dermatomyositis at times appears to merge with the syndrome *chronic polymyositis* which is considered in the next chapter

Treatment There is no measure which provides uniform success in the treatment of dermatomyositis Aspirin or sodium salicylate often provides relief of pain In a number of instances treatment with ACTH or cortisone or cortisonelike compounds has produced some benefit The details of therapy with these agents are considered in the section on systemic lupus erythematosus

tients the joints show deformities analogous to those of rheumatoid arthritis Hoarseness may result from changes in the larynx Dysphagia is probably the most frequent gastrointestinal disturbance but there may be epigastric pain nausea or vomiting The chest expansion may be limited by scleroder matous changes in the skin of the thorax and fine interstitial pulmonary fibrosis occurs Fibrous tissue may replace heart muscle and result in cardiac failure In an occasional case of scleroderma rapidly progressive vascular lesions in the kidney are ac companied by severe hypertension and lead to fatal *renal insufficiency* The thickening of the skin may remain localized or the entire body may become implicated Occasionally symptoms such as dys phagia or dyspnea arise from visceral lesions at a time when the changes in the skin are minimal Contractures can lead to invalidism and food intake may be difficult because of limited movement of the jaws The disease can regress spontaneously or become stationary Death attributable specifically to cardiac pulmonary or renal lesions may occur More commonly death results from an intercurrent infection In a number of patients scleroderma remains primarily a disorder of the skin for many years

In the advanced case the characteristic skin induration is easily recognized Early the occur rence of edema arthralgia and vasomotor disturb ances (Raynaud s phenomenon) should lead to consideration of this disease Focal and diffuse scleroderma may be encountered in dermatomyo sitis which is recognized primarily by the associated muscle tenderness Scleredema adultorum (p 1708) may be difficult to distinguish from scleroderma in an early stage There is a rare familial disorder termed *Werner s syndrome* or the closely related *Rothmund syndrome* in which sclerodermatous changes in the extremities are associated with bi lateral juvenile cataracts hypogonadism progeria and a tendency to diabetes mellitus

Laboratory Data The routine blood examination usually shows no abnormality other than an elevated erythrocyte sedimentation rate Frequently there is slight albuminuria The serum albumin is reduced and the serum globulin tends to be increased Sig nificant increases in urinary creatine excretion are found only in those cases where there is muscle alteration identical with that seen in dermatomyo sitis Roentgenograms may show areas of osteo porosis and destructive lesions of the terminal phalanges Likewise changes in the esophagus small bowel colon lung and heart may be dis closed In certain cases *studies with barium demon* strate malfunction of the esophagus even though there may be no complaint of dysphagia The small bowel pattern likewise may be abnormal radiologi cally in the absence of intestinal symptoms Biopsy of the affected skin often discloses the characteristic lesion

Treatment There is no *specific treatment* Cervi codorsal sympathectomy has given temporary bene fit in *selected cases with pronounced* vasomotor disturbances but usually has *not resulted in regres* sion of lesions The judicious use of physiotherapy to prevent and overcome contractures *and to main* tain and to improve muscle strength *seems to be* the most reasonable form of treatment at this time ACTH and cortisone or related steroids *may* be employed in the management of this disease The results of this form of treatment are inconsistent and occasionally the hormones appear to aggravate the process The schedules for hormone therapy considered in the section on treatment of systemic lupus (p 1702) would apply to the management of scleroderma

DERMATOMYOSITIS

Definition This is a chronic often fatal disorder affecting primarily the skin and striated muscle The etiology is unknown Depending upon the manifestations of the disease other names have been applied to it These include *polymyositis dermatomucomyositis neuromyositis* and *poikilo dermatomyositis*

Dermatomyositis has been observed in whites Negroes and Orientals Individuals of any age may be affected but it is most frequent at ages between ten and fifty years There is no sex predominance

Pathology Gross anatomic findings are usually meager One may detect changes in striated mus cles a cutaneous eruption and occasionally lymph node and splenic enlargement The histologic changes in the skin are not characteristic The microscopic findings in the muscle may be diffuse or focal Sometimes they are confined to a segment of a single muscle The muscle fibers show pro liferation of sarcolemmal nuclei occasional giant cells and varying degrees of atrophy necrosis loss of striation hyalinization fragmentation or fatty degeneration A moderate infiltration with lympho cytes and histocytes may be present in interstitial tissue which frequently is increased in amount In the small arteries and arterioles the walls may be thickened and the lumens narrowed

Rarely changes similar to those occurring in skeletal muscle are present in the myocardium Perineural cellular infiltrations have been observed

Clinical Manifestations The onset is insidious Not infrequently a recent upper respiratory infec *tion precedes the earliest symptoms* Patchy ery thema or edema myalgia or vasomotor disturbances may be presenting symptoms

The skin manifestations are extremely diverse Most common are erythematous eruptions Purpuric

in establishing the diagnosis A decrease in the mean duration of the action potential appears to be one of the more common disturbances The absence of fibrillation potentials helps to differentiate it from spinal muscular atrophy and lesions of the peripheral nerves (see p 504)

The diagnosis of chronic polymyositis is difficult when there is weakness without any atrophy or change in consistency of muscles Whenever the weakness is symmetrical and predominantly proximal in the extremities this disorder should be considered

It should be evident that some cases of chronic polymyositis do not differ significantly from instances of dermatomyositis However other cases of polymyositis bear only slight resemblance to the latter It is not unusual for these patients to be labeled as having muscular dystrophy progressive muscular atrophy polyneuritis or hysteria A few cases have been described in which enlargement of the calf muscles appeared in connection with polymyositis in children making difficult the distinction between muscular dystrophy and polymyositis Suitable biopsies of the affected muscles will usually clarify the situation

More than half the cases of chronic polymyositis improve after treatment with ACTH or cortisone and related compounds The manner of therapy described in the section on systemic lupus erythematosus may be consulted It is important to recognize that response to therapy may be delayed in this disorder Treatment should be continued for 2 or 3 months before an attempt to evaluate its efficacy

WEGENER S GRANULOMATOSIS

The rare disease Wegener's granulomatosis has certain clinical and pathologic similarities to polyarteritis nodosa It affects both sexes equally and persons of all ages are susceptible In the diffuse form of the disease the major pathologic changes are found in the respiratory tract and kidneys Most characteristic are necrotizing granulomas in the lung or in ulcerated lesions of the upper respiratory tract (nose sinuses pharynx) Vasculitis of pulmonary arteries and veins is almost a constant feature Both vasculitis and granulomas may be widely distributed throughout the body In the kidneys there is a focal glomerulitis giving rise to necrosis of portions of glomerular tufts Other glomeruli may show epithelial crescents

Clinically this disease should be suspected when ulcerated lesions of the upper respiratory tract are found in persons in whom no other etiology seems likely Cough and pulmonary infiltrations may be the initial findings Fever and loss of weight are prominent Other symptoms and signs depend upon the distribution of the vascular and granulomatous lesions Anemia and leukocytosis are usual findings Transient eosinophilia is common The urine may contain protein red blood cells leukocytes and casts There may be hyperglobulinemia

There is no known treatment for this disease Because some cases seem to result from hypersensitivity ACTH and adrenal steroids have been tried with equivocal results

Death from secondary bacterial infection or from renal insufficiency is frequent

WEBER CHRISTIAN DISEASE

Introduction Weber Christian disease or relapsing febrile nodular nonsuppurative panniculitis is a disorder characterized by recurrent bouts of fever and crops of subcutaneous nodules resulting from focal necrosis of fatty tissue This disease is three times as common in females as in males Most cases are observed in individuals between the ages of twenty and forty

Manifestations Most striking is the tendency of this disease to exacerbations and long remissions Fever usually appears with the onset of skin manifestations The duration and magnitude of the fever are variable The subcutaneous lesions are freely movable raised and tender and there is erythema of the overlying skin Usually the lesions are less than 1 cm in diameter but they coalesce to form larger lesions They are most common on the thighs but may occur on the trunk and upper extremities With healing depression of the skin frequently is observed The nodules consist of necrotic fatty tissue infiltrated with lymphocytes plasma cells and fat laden macrophages Foreign body giant cells are often present Occasionally small vessels (arteries and veins) show leukocytic infiltration

The fever and cutaneous manifestations may appear disappear for intervals of months or years and then recur The disease may continue for 10 years During the febrile periods the leukocyte count may be normal elevated or depressed In patients with leukopenia splenomegaly is sometimes present Occasionally there is a mild anemia

Biopsy wounds are prone to heal slowly A few patients have died as a result of the disease Autopsy studies have shown fatty metamorphoses with central necrosis in liver lobules Characteristic granulomatous lesions have been encountered in the fat surrounding the trachea the pericardium the pancreas adrenals kidneys the mesentery omentum and bone marrow

Diagnosis Recurrent fever subcutaneous nodules and the biopsy findings should establish the diagnosis The cutaneous lesions may be difficult to differentiate morphologically from the lesions of

263 MISCELLANEOUS AND RARER DISEASES OF CONNECTIVE TISSUE

B V Jager

CHRONIC POLYMYOSITIS

This affliction of muscle may appear at any age. It is perhaps most frequently observed to begin in the first to fourth decades There is no sex predominance Apart from low grade fever and loss of weight constitutional symptoms are slight Occasionally there is mild dysphagia A few patients have Raynaud s phenomenon Early in the illness there may be aching or tenderness of the muscles

Most often it is the symmetrical changes in the muscles of the pelvic girdle and thighs which produce the earliest symptom of weakness This may lead to difficulty in climbing stairs or in rising from a sitting position Subsequently the muscles of the upper arm and shoulder girdle become involved In certain instances the weakness is first noted in this region As the disease continues there may be obvious fibrosis and atrophy of muscles Weakness may be marked at a time while the muscle mass is still normal in consistency and in amount In some patients the process extends to affect nearly all of the skeletal muscles

The course is highly variable Often it is insidiously chronic and progressive or it may be a smoldering process which is interrupted by episodes of intense activity followed by a return to a gradual course Spontaneous remissions usually incomplete are frequent The process may stabilize in such a remission with only a limited degree of localized muscle weakness as a residual

Upon biopsy the affected muscles demonstrate changes which do not differ significantly from those of dermatomyositis

A few of these patients have a relative and an absolute increase in eosinophilic leukocytes The blood otherwise usually is unremarkable and the urine examination is negative These patients show varying degrees of creatinuria in addition to a reduction in urinary creatinine The amount of creatine in the urine may not exceed the value for normal subjects but usually it is increased

A number of electromyographic abnormalities have been observed in polymyositis When multiple sites are examined the observations can be helpful

histologic confirmation of this diagnosis but also gives relief of discomfort ACTH and cortisone may be effective in relieving the symptoms Therapy with these agents should be maintained for a number of weeks since exacerbations often are observed when this form of treatment is employed for brief periods and then is discontinued

264 THE ERYTHEMAS

B V Jager

This chapter contains a brief description of erythema multiforme erythema multiforme exudativum erythema nodosum erythema induratum and nodular vasculitis Perhaps hypersensitivity reactions are responsible for all of these disorders

ERYTHEMA MULTIFORME

Erythema multiforme is a symmetrical eruption which is thought to represent an allergic response to drugs or to bacterial infections The skin lesions may be macular papular or vesicular in character The distribution is varied but frequently the wrists backs of the hands lower legs and dorsal aspects of the feet are affected The mucous membranes are implicated in many instances so that erythematous and vesicular lesions may be encountered on the lips in the mouth and pharynx, and occasionally in the genital region There is usually local discomfort at the site of the lesions Occasionally there is a concomitant systemic reaction with fever and arthralgia The appearance of the eruption varies and it may be confused with many other types of dermatologic disorders

In some instances of acute rheumatic fever a cutaneous eruption termed *erythema marginatum* is present Here there are red elevated flat topped lesions These usually enlarge peripherally and may vary from pink to violet in color

Another type of erythema multiforme is termed the *iris* variety These lesions are vesicopapules which spread peripherally forming rings of various sizes and shapes The margins are often highly colored giving the lesion the appearance of a target

The duration of the cutaneous lesions seldom exceeds 4 weeks Recurrences may appear long after disappearance of the original skin rash

Usually no therapy is indicated Effort should be made to determine if any drug sensitization is responsible for the difficulty Such a drug should not be given to the patient at a future time For more severe cases there may be improvement with use of any one of the following in suitable dosage

sarcoid erythema induratum (Bazin's disease) nodular vasculitis local thrombophlebitis and erythema nodosum In diffuse symmetrical lipomatosis and in adiposis dolorosa the subcutaneous indurations sometimes are similar to those seen in Weber Christian disease

Treatment Sulfonamides and antibiotics are of no benefit Cortisone prednisone prednisolone or ACTH in some cases produce symptomatic relief with disappearance of fever and cutaneous nodules The treatment program described in the section on lupus erythematosus may be employed

SCLEREDEMA ADULTORUM

Introduction Scleredema adultorum is a rare disorder which occurs more often in females than in males It may appear at any age but is most frequent in the third decade It is a benign self limited disease characterized by edema and induration of the skin Scleredema was described by Buschke in 1902 and previously by Piffard in 1876 who termed the disorder *sclerasis*

Clinical Manifestations In the majority of cases there is a history of a beta hemolytic streptococcal infection 1 to 3 weeks preceding the disease Usually the onset is characterized by edema which begins in the neck and progresses over 1 to 3 weeks to involve the face trunk upper extremities and sometimes the lower extremities The hands and feet are not affected Occasionally there is an erythematous eruption at the onset The tongue and skeletal muscle may be implicated Effusions into joints or pleural space have been observed

The skin of involved regions usually retains its normal appearance but may be pale and indurated There are no changes in pigmentation Histologically sections of skin show swelling of the collagen bundles of the corium These bundles may be separated by clear spaces the contents of which sometimes are stainable with the dye cresyl violet

No abnormalities are found on laboratory examination The duration of the disease is variable It may last a few months to several years Complete recovery is the rule

Diagnosis The history of the preceding respiratory infection the finding of induration of the skin neck shoulders and upper arms—with sparing of the hands—and the absence of laboratory abnormalities should suggest the diagnosis At times this disorder may be confused with the early stages of diffuse scleroderma In scleroderma however there may be pigmentation or depigmentation of the skin vasomotor disturbances and involvement of the hands Scleredema may be confused with dermatomyositis in the early stages but the course of the two diseases is distinct

TEMPORAL ARTERITIS

Temporal arteritis also called *cranial arteritis* or *giant cell arteritis* is a vascular disease affecting branches of the carotid arteries of persons beyond the age of fifty five years Clinically the temporal artery is usually prominently involved Both sexes are equally vulnerable to this uncommon affliction which is self limited with recovery to be anticipated within 2 to 12 months

The affected arteries have narrowed lumens which occasionally are occluded by thrombi Rarely there are aneurysmal dilatations of arteries Histologically the vessels show a striking concentric proliferation of fibroblasts in the intima It is this feature which often results in a great reduction in the size of the lumen Much of the muscle and elastic tissue of the media is destroyed There may be fibrinoid necrosis in this area Also in the media there is an infiltration with histiocytes and large giant cells of the foreign body type Post mortem examinations on affected subjects have disclosed that the arterial lesions can be more disseminated than would be expected from clinical observations Characteristic histologic lesions can occur in the following arteries the aorta the innominate internal and external carotid subclavian vertebral temporal ophthalmic pulmonary coronary celiac renal iliac and popliteal

There often are mild systemic symptoms prior to and during the course of this illness These include low grade fever malaise anorexia loss of weight and aching of muscles and joints Most patients complain of excruciating headache localized to one or both temporal regions This is followed by redness and heat of the skin overlying the tender temporal artery The pulsations of this vessel initially present decrease and usually disappear as the disease progresses Ischemia in various areas arising from the intimal proliferation accounts for many of the later manifestations About one third of the patients develop impaired vision in one or both eyes This may result in total and permanent blindness There may be tinnitus and vertigo Reduction in hearing may appear early in the illness and then persist after recovery from the systemic illness Thrombosis of other branches of the internal carotid and vertebral arteries can result in extensive brain injury Ulcerations may appear in the skin along the temporal vessels or in the nose and mouth Rarely there are palpable aneurysms in the neck or chest

Laboratory studies usually will disclose slight anemia an elevated sedimentation rate and moderate leukocytosis

Various forms of therapy for this disorder have been attempted Section of the painful temporal artery not only provides a segment of vessel for

loma venereum (p 1096) It has been observed in *trichophytosis leprosy (p 954)* Carrion s disease (p 915) and other infections Erythema nodosum occasionally is present in sarcoidosis It also may be associated with drug hypersensitivity reactions Many instances were observed when sulfathiazole was used extensively Frequently no etiologic fac tor can be detected

Pathologically the lesions are remarkably similar in appearance in spite of the diversified agents that may elicit their appearance The well developed lesion consists histologically of granulomas of histio cytes lymphocytes and foreign body giant cells in the subcutaneous connective tissue and fat There often are fibrinoid changes in the collagen and the vessels may show mild inflammatory changes Leukocytes in the walls of small arteries and venules may suggest the diagnosis of polyarteritis nodosa (p 1698)

The characteristic skin lesion of erythema nodosum is a raised tender erythematous nodule on the lower extremities The lesions usually are ovoid and vary from 1 to 5 cm in diameter It is common for several lesions to be present simul taneously Usually these appear at different times during the illness As the lesions persist the over lying skin initially red becomes blue or brown suggesting a bruise

Fever arthralgia and *arthritis* are common associated findings Occasionally there are purpuric lesions The illness usually lasts 1 to 3 weeks but may be longer After intervals of months or years the condition may recur

Laboratory studies usually show an elevated erythrocyte sedimentation rate and a moderate leukocytosis Eosinophilia is uncommon except in coccidioidomycosis Albuminuria during the acute stage is frequent Roentgenograms of the chest taken late in the illness often show considerable degrees of hilar adenopathy

The diagnosis of this disorder usually is not dif ficult Occasionally it may be confused with nodular panniculitis (Weber Christian disease p 1707) nodular vasculitis and erythema induratum

Usually no specific treatment is indicated In severe or long lasting illness good responses may be expected when ACTH or cortisone or related steroids are given for periods of several weeks in adequate doses

ERYTHEMA INDURATUM (Bazin s Disease)

Erythema induratum is thought to represent a focal cutaneous or subcutaneous tuberculous infec tion in which hypersensitivity to products of the tubercle bacilli may have a role The affected sub jects usually are females below the age of thirty years The skin lesions are to be found on the legs below the knees They begin as soft and often tender subcutaneous infiltrates with red or purple discoloration of the overlying skin Later there may be induration of the nodules with attachment to the skin The nodules tend to persist for long periods and may ulcerate or may undergo spon taneous absorption Healing of both ulcerated and nonulcerated lesions often is accompanied by scar ring pigmentation and depression of the overlying skin

The nodules tend to recur over long periods There often is very little systemic reaction with the skin changes Most individuals with this disorder *display extremely severe cutaneous reactions to* tuberculin

Pathologically sections of the nodules may re veal typical tubercles caseation necrosis fibrosis lymphocytic infiltration and vasculitis of arteries and veins Occasionally no typical tubercles are to be seen Tubercle bacilli should be demonstrated either by stains of histologic sections or by culture or inoculation of guinea pigs with portions of the nodule removed at biopsy If bacteriologic and his tologic proof of tuberculosis is lacking a specific diagnosis of erythema induratum is not justified Erythema nodosum Weber Christian disease and nodular vasculitis are considered in the differential diagnosis

Antituberculous therapy with isoniazid strepto mycin or para aminosalicylic acid is indicated when the diagnosis is established Response to therapy often requires many months

NODULAR VASCULITIS

Females in the age range of thirty to fifty years seem to be particularly disposed to this disorder Some of them have been found to have evidence of vascular disease such as acrocyanosis Raynaud s phenomenon or mild hypertension The lesions of nodular vasculitis usually are confined to the legs below the knees Often both legs are affected at the same time The nodules appear in crops of four or five They persist for a number of weeks and then disappear for a period of several months only to recur The nodules are raised tender and are red or purple Some undergo ulceration but most heal with residual scarring pigmentation and de pression of the skin Often they produce consid erable discomfort

Pathologically the typical nodules show vascu litis of arteries and veins fibrosis and infiltration with lymphocytes histiocytes and foreign body giant cells There are no typical tubercles

It should be evident that nodular vasculitis has a close clinical and pathologic similarity to erythema induratum Often they cannot be distinguished unless tubercle bacilli are demonstrated Clinically

ACTH cortisone hydrocortisone prednisone and prednisolone

ERYTHEMA MULTIFORME EXUDATIVUM

Erythema multiforme exudativum is a disorder of varying severity affecting the skin eyes oral cavity and genital region It is thought to include diseases designated as *Hebra s disease Stevens Johnson syndrome Klauder s disease* ectodermosis erosiva pluriorificialis dermatostomatitis and perhaps Behcet s syndrome

The *etiology* is unknown In a few instances *sensitivity to* sulfonamides or other drugs may have been responsible It has been suggested that a virus is *the* causative agent but convincing proof is lacking Males are affected five times as frequently as *females* The majority of cases appear during the first three decades of life This disease is more com*mon in the* winter and spring

The *onset* usually is abrupt and is associated with chills fever headache and sore throat Conjunctivitis and stomatitis soon ensue Later there may be genital lesions and various types of skin eruptions Bronchopneumonia may occur There frequently is arthralgia but swelling of joints is uncommon The duration of the disorder is highly variable but the usual course is 2 to 8 weeks Recurrences are frequent and may be spaced at short intervals or several months to several years apart Permanent blindness may develop following corneal ulcerations

The *skin lesions* commonly affect the hands and feet but may involve the entire body the scalp usually being spared Palmar and plantar lesions are relatively common The lesions may be erythematous purpuric vesicular or bullous The papular erythematosus lesions often assume a purple hue and may be circular with uninvolved central portions (*erythema iris*) or may be serpiginous (*erythema gyratum*) The vesicles and bullae after rupture usually become crusted and hemorrhagic Often new crops of skin eruptions appear during the illness varied stages of their development being present simultaneously

The earliest *mouth lesions* are vesicular Later these rupture and a diffuse membranous stomatitis results The lips usually are swollen ulcerated and covered with hemorrhagic crusts Swallowing of fluid or food may be impossible

In the eyes there is a diffuse conjunctivitis with edema of the lids Corneal ulcerations may appear and lead to subsequent ophthalmitis and blindness Iritis may be present in the absence of corneal ulceration

Ulcerations of the scrotum and the glans penis are not infrequent There may be an associated urethritis In females the genital lesions are represented by a vulvovaginitis Occasionally ulcers appear in the perianal region

Clinical and radiologic evidence of pulmonary infiltration is relatively common

The blood examination frequently is normal There may be leukocytosis or rarely leukopenia Occasionally there is an absolute eosinophilia During the febrile period albuminuria often is present

Not all patients with this syndrome present all of the manifestations described above Moreover the severity of the disease varies greatly from person to person The diagnosis is established by the presence of a profound systemic reaction in addition to eye mouth skin and genital lesions

The *differential diagnosis* would include human infection with hoof and mouth virus (p 1104) chickenpox (p 1058) acute pemphigus and smallpox (p 1060) A biopsy of the skin usually will be sufficiently characteristic as to distinguish between pemphigus and the disorder under consideration The mouth lesions may simulate Vincent s angina or diphtheria Reiter s syndrome (p 1154) has many of the features of erythema multiforme exudativum However joint involvement is usually severe in Reiter s disease whereas it is minimal or absent in the syndrome under consideration here

Treatment is unsatisfactory Various antibiotics have been employed They should be useful in combating secondary infections when these are present In a number of instances benefit results from administration of ACTH or of cortisone and related steroids Use of these agents as outlined under Systemic Lupus Erythematosus (p 1702) deserves further trial since this disease in a severe form or with secondary infections may have a fatal outcome

ERYTHEMA NODOSUM

Erythema nodosum is a brief febrile illness characterized by cutaneous painful nodules—commonly on the legs—arthralgia or arthritis and malaise It generally is regarded as a reaction of hypersensitivity to a variety of agents In North America it most frequently follows in the wake of *group A beta hemolytic streptococcal infections* This is supported by historical evidence of antecedent pharyngitis the frequent presence of streptococci in the throat the commonly elevated antistreptolysin O titer and the observation that killed streptococci injected into subjects with this disorder elicit greater febrile and local reactions than in normal subjects In the Southwestern part of the United States erythema nodosum commonly is associated with primary coccidioidomycosis (p 988) This disorder may also occur early in tuberculosis and at the time when the tuberculin test has become positive Similarly it may appear in lymphogranu

loma venereum (p 1096) It has been observed in trichophytosis leprosy (p 934) Carrion's disease (p 915) and other infections Erythema nodosum occasionally is present in sarcoidosis It also may be associated with drug hypersensitivity reactions Many instances were observed when sulfathiazole was used extensively Frequently no etiologic factor can be detected

Pathologically the lesions are remarkably similar in appearance in spite of the diversified agents that may elicit their appearance The well developed lesion consists histologically of granulomas of histiocytes lymphocytes and foreign body giant cells in the subcutaneous connective tissue and fat There often are fibrinoid changes in the collagen and the vessels may show mild inflammatory changes Leukocytes in the walls of small arteries and venules may suggest the diagnosis of polyarteritis nodosa (p 1698)

The characteristic skin lesion of erythema nodosum is a raised tender erythematous nodule on the lower extremities The lesions usually are ovoid and vary from 1 to 5 cm in diameter It is common for several lesions to be present simultaneously Usually these appear at different times during the illness As the lesions persist the overlying skin initially red becomes blue or brown suggesting a bruise

Fever arthralgia and *arthritis* are common associated findings Occasionally there are purpuric lesions The illness usually lasts 1 to 3 weeks but may be longer After intervals of months or years the condition may recur

Laboratory studies usually show an elevated erythrocyte sedimentation rate and a moderate leukocytosis Eosinophilia is uncommon except in coccidioidomycosis *Albuminuria during the acute* stage is frequent Roentgenograms of the chest taken late in the illness often show considerable degrees of hilar adenopathy

The diagnosis of this disorder usually is not difficult Occasionally it may be confused with nodular panniculitis (Weber Christian disease p 1707) nodular vasculitis and erythema induratum

Usually no specific treatment is indicated In severe or long lasting illness good responses may be expected when ACTH or cortisone or related steroids are given for periods of several weeks in adequate doses

ERYTHEMA INDURATUM (Bazin's Disease)

Erythema induratum is thought to represent a focal cutaneous or subcutaneous tuberculous infection in which hypersensitivity to products of the tubercle bacilli may have a role The affected subjects usually are females below the age of thirty years The skin lesions are to be found on the legs below the knees They begin as soft and often tender subcutaneous infiltrates with red or purple discoloration of the overlying skin Later there may be induration *of the nodules with attachment to* the skin The nodules tend to persist for long periods and may ulcerate or may undergo spontaneous absorption Healing of both ulcerated and nonulcerated lesions often is accompanied by scar*ring pigmentation and depression of the overlying* skin

The nodules tend to recur over long periods There often is very little systemic reaction with the skin changes Most individuals with this disorder display extremely severe cutaneous reactions to tuberculin

Pathologically sections of the nodules may reveal typical tubercles caseation necrosis fibrosis lymphocytic infiltration and vasculitis of arteries and veins Occasionally no typical tubercles are to be seen Tubercle bacilli should be demonstrated either by stains of histologic sections or by culture or inoculation of guinea pigs with portions of the nodule removed at biopsy If bacteriologic and histologic proof of tuberculosis is lacking a specific diagnosis of erythema induratum is not justified *Erythema nodosum* Weber *Christian disease* and nodular vasculitis are considered in the differential diagnosis

Antituberculous therapy with isoniazid streptomycin or para aminosalicylic acid is indicated when the diagnosis is established Response to therapy often requires many months

NODULAR VASCULITIS

Females in the age range of thirty to fifty years *seem to be particularly disposed to this disorder* Some of them have been found to have evidence of vascular disease such as acrocyanosis Raynaud's phenomenon or mild hypertension The lesions of nodular vasculitis usually are confined to the legs below the knees Often both legs are affected at the same time The nodules appear in crops of four or five They persist for a number of weeks and then disappear for a period of several months only to recur The nodules are raised tender and are red or purple Some undergo ulceration but most heal with residual scarring pigmentation and depression of the skin Often they produce considerable discomfort

Pathologically the typical nodules show vasculitis of arteries and veins fibrosis and infiltration with lymphocytes histiocytes and foreign body giant cells There are no typical tubercles

It should be evident that nodular vasculitis has a close clinical and pathologic similarity to erythema induratum Often they cannot be distinguished unless tubercle bacilli are demonstrated Clinically

nodular vasculitis tends to occur in a slightly older age group the lesions tend to be smaller and they are less likely to ulcerate than those of erythema induratum

ACTH or cortisone and related compounds often lead to disappearance of skin lesions in nodular vasculitis

265 DISORDERS OF THE JOINTS

Laurence E Shulman and Joseph J Bunim

Terms used to designate abnormal conditions of the joints are numerous frequently ambiguous and only too often used interchangeably *Rheumatism* is derived from the Greek *rheumatismos* this was believed to be an evil humor originating in the brain and flowing to the joints where it produced pain Currently rheumatism is used most as a generic term often loosely to indicate pain stiffness or deformity of joints muscles and related structures The *rheumatic diseases* embrace a large group of diseases of the musculoskeletal system in which alterations take place in the articular structures (synovial tissue joint capsule cartilage and bone) and/or in the connective tissue surrounding the joints as in tendons or in various other organs of the body Because of the prominent involvement of this tissue in these disorders it is becoming more fashionable and rightly so to designate them *diseases of connective tissue* The term *arthritis* is usually used to denote any disorder of joints although more properly its use should be restricted to those disorders of joints which are inflamed A joint disorder not accompanied by inflammation is frequently called an *arthropathy* If however the pain tenderness or stiffness originates from a nonarticular structure such as muscle tendon ligament bursa or subcutaneous fat the condition is often labeled *fibrositis* Wherever possible more specific terminology such as *tendinitis bursitis* or *panniculitis* should be used

Prevalence Surveys conducted by the Public Health Service show that over 10 million persons suffer from some form of rheumatism indicating that it is one of the most common causes of chronic illness in the United States Rheumatic disorders rank second to nervous and mental diseases as causes of temporary and permanent disability Of the 10 million people with rheumatic complaints almost one half or 4 5 million have arthritis over 10 per cent or 1 143 000 are partially disabled and almost 2 per cent 190 000 are completely disabled More than half the disabled are under forty five years of age One quarter of the 10 million changed their jobs presumably because of their rheumatic symptoms In other countries the toll from rheumatism is even greater In Great Britain for example half the population suffers from nondisabling rheumatism 7 per cent are incapacitated by it for at least 1 day each year and one sixth of the total industrial disability is ascribed to rheumatism Similarly in Switzerland arthritis is

responsible for 16 per cent of all sickness reports to insurance companies and the same proportion of total absence from work. Among the major categories of chronic disease rheumatism cripples most and kills least. Much of the crippling occurs in young people during their productive years. The economic loss and personal unhappiness which result make rheumatism a national health problem.

Classification

Difficulties arise when one attempts to set up a workable and logical classification of joint diseases. It cannot be constructed satisfactorily on etiologic grounds when the cause of so many forms of joint disease is unknown. Separation on the basis of pathologic change is often helpful, yet it may actually restrict knowledge, since the connective tissues are capable of reacting to injurious stimuli in only a limited number of ways. Differentiation on clinical grounds alone may be similarly unsatisfactory because widely divergent pathologic forces may give rise to an identical clinical picture. Division into acute and chronic categories is also hazardous because acute arthritides may become chronic, and chronic arthritides may begin acutely or have acute exacerbations.

Thus it is clear that the state of our knowledge or lack of it permits no complete or satisfactory classification. Most attempts at clarifying joint diseases include etiologic, pathologic and clinical factors. The American Rheumatism Association has approved a classification which conforms to the phraseology of "The Standard Nomenclature of Disease," thus providing uniformity. Wherever possible its use is recommended. The accompanying outline (Table 134), however, is offered as a more useful guide to differential diagnosis because it is based largely on pathogenetic features.

Approach to the Patient with Joint Disease

Every effort should be made to establish an accurate and precise diagnosis in patients with joint complaints. This is essential for proper management.

History. The *age* of the patient is not as important in diagnosis as was formerly thought. In the elderly, arthritis was assumed to be degenerative joint disease; in the young or middle aged, rheumatoid arthritis. Actually the chance of a person's having rheumatoid arthritis increases up to the age of fifty-five years, after which it remains stationary; conversely, degenerative joint disease can begin as early as the second decade.

Females are more likely to have Heberden's nodes (10:1), systemic lupus erythematosus (8:1) or peripheral rheumatoid arthritis (2:1), whereas rheumatoid spondylitis is decidedly more common in men (9:1).

It is important to know the *occupation* and *avocations* of the arthritic patient. Injury at work or at play gives rise to such conditions as "housemaid's knee," "nurse's feet," "boxer's bursitis," "student's elbow," "baseball fingers" and "weaver's bottom." Trauma can also play an important role in the selection of the sites affected in degenerative joint disease.

Careful attention must also be paid to the *family history*. The family incidence of gout varies from 10 to 18 per cent. Moreover, 25 per cent of the nongouty relatives of patients with gout have hyperuricemia. Another illustration is the familial nature of idiopathic Heberden's nodes, which is also controlled by a single autosomal gene; in this case it is dominant in the female and recessive in the male.

"Growing pains" in childhood may direct one's attention to rheumatic fever or juvenile rheumatoid arthritis. Repeated throat infections, especially if known to be caused by the beta hemolytic streptococcus, also point to rheumatic fever. A history of unexplained fever, skin disorders, serositis and hematologic abnormalities may suggest that the arthritis is merely one manifestation of a collagen vascular disorder. Urethritis may precede arthritis and conjunctivitis in Reiter's syndrome or gonorrhea. At times renal calculi may appear before gouty arthritis. Nephritis may antedate arthralgia in systemic lupus erythematosus. Clearly, a history of trauma to a joint or arthritis in the remote past must be sought, because such an event may be related to the present rheumatic illness.

Meticulous inquiry into *events immediately preceding the onset* of the arthritis yields important clues to diagnosis. An antecedent infection of one or more organs, especially if accompanied by bacteremia, indicates that the arthritis may be infectious. Streptococcal tonsillitis or pharyngitis preceding the arthritis by 1 to 4 weeks strongly suggests rheumatic fever. Prior injections of penicillin or foreign protein, especially if accompanied by fever or urticaria, bring to mind the arthritis of serum sickness. Frequently rheumatoid arthritis is preceded by overwork, emotional stress or exposure to a cold damp environment and is ushered in by constitutional symptoms—feverishness, malaise, fatigability, anorexia, parasthesias and weight loss. Such constitutional symptoms do not antedate the onset of degenerative joint disease.

The *mode of onset* of the arthritis should be ascertained. A joint disorder may appear explosively (as in rheumatic fever), subacutely (as in rheumatoid arthritis) or insidiously (as in degenerative joint disease). There are many exceptions, however

Table 134 CLASSIFICATION OF DISORDERS OF JOINTS

I Arthritis caused by specific infection
- *A* Pyogenic arthritis
  - 1 Staphylococcus
  - Streptococcus
  - 3 Pneumococcus
  - 4 Gonococcus
  - 5 Meningococcus
- *B* Brucellosis (arthritis rare arthralgia common)
- *C* Tuberculosis
  - 1 Arthritis
  - 2 Spondylitis (Pott s disease)
- *D* Syphilis
  - 1 Congenital
    - Symmetrical synovitis (Clutton joints)
    - *b* Osteochondritis (Parrot s pseudoparalysis)
  - Acquired (tertiary)
    - Synovitis
    - *b* Gummatous
- *E* Less common forms of infectious arthritides
  - 1 Bacteria
  - 2 Fungi
  - 3 Viruses

II Arthritis possibly caused by specific infection
- *A* Reiter s syndrome

III Arthritis as a sequel to specific infection
- *A* Rheumatic fever

IV Arthritis caused by hypersensitivity to foreign agent
- *A* Drug reactions
- *B* Serum sickness
- *C* Anaphylactoid purpura

V Arthritis in widespread inflammatory connective tissue disease cause unknown
- *A* Rheumatoid arthritis and variants
  - 1 Adult peripheral type
  - 2 Juvenile rheumatoid arthritis (Still disease)
  - 3 Rheumatoid spondylitis (Marie-Strümpell disease)
  - 4 Psoriatic arthritis
  - 5 Felty syndrome
  - 6 Arthritis with ulcerative colitis
  - Sjögren syndrome
- *B* Collagen vascular disorders
  - 1 Systemic (disseminated) lupus erythematosus
  - Polyarteritis (periarteritis nodosa)
  - 3 Progressive systemic sclerosis (scleroderma)
  - 4 Dermatomyositis
- *C* Granulomatous
  - 1 Sarcoidosis
  - 2 Erythema nodosum

VI Arthritis caused by metabolic or endocrine disorders
- *A* Gout
- *B* Ochronosis
- *C* Acromegaly

VII Degenerative joint disease (osteoarthritis)
- *A* Generalized
- *B* Localized
  - 1 Hereditary (such as Heberden s nodes)
  - 2 Secondary to previous trauma or infection
  - 3 Secondary to faulty body mechanics
  - 4 Unknown cause

VIII Arthritis caused by trauma to joints
- *A* Direct trauma
- *B* Internal mechanical derangement of joint

IX Neurogenic arthropathy (Charcot joint)
- *A* Tabes dorsalis
- *B* Syringomyelia
- *C* Neuropathy of diabetes mellitus
- *D* *Peripheral nerve injuries*
- *E* Leprosy

X Arthritis caused by bleeding into joints
- *A* Direct trauma
- *B* *Disorders of blood coagulation*
  - 1 Hemophilia and variants

XI Neoplasm of joints
- *A* Cyst
- *B* Lipoma
- *C* Hemangioma
- *D* Synovioma
- *E* Giant cell tumor

XII Arthritis secondary to lesions of bone
- *A* Aseptic necrosis of bone
  - 1 Primary of unknown cause
  - 2 Secondary to
    - *a* Trauma
    - *b* Vascular occlusion
- *B* Neoplasms of bone
  - 1 Primary
  - Metastatic to bone
- *C* Osteochondromatosis
- *D* Osteochondritis dissecans
- *E* Endocrine diseases of bone

XIII Hypertrophic osteoarthropathy

XIV Miscellaneous arthritis
- *A* Shoulder hand syndrome
- *B* Palindromic rheumatism
- *C* Intermittent hydrarthrosis
- *D* Psychogenic rheumatism (hysterical arthritis)

XV Periarticular conditions (*nonarticular rheumatism*)
- *A* Fibrositis
- *B* Tendonitis
- *C* Bursitis
- *D* Tendon sheath cyst (ganglion)
- *E* Myositis
- *F* Neuritis
- *G* Panniculitis

and the interpretation by patients of the acuteness of an illness varies greatly

It is also important to obtain a full characterization of the patient s joint *pain* The pain of acute gouty arthritis for example is constant severe boring and *not influenced by position or time of day* In contrast the discomfort in degenerative joint disease is usually transient mild and superficial it emerges with attempted movement after a period of rest in one position and disappears readily after brief exercise In a different manner the patient with rheumatoid arthritis complains of morning stiffness which disappears gradually only after several hours of activity whereas the pains in the affected joints may become more severe as the day progresses Similarly pain from trauma or deformities may increase as the day wears on

The patient should also be asked about the occurrence of other signs which reflect articular inflammation namely *excessive heat discoloration of the skin tenderness* or *swelling* of the involved joint One must determine whether the swelling is confined to one or more joints near joints but not in them or spread more diffusely

Valuable diagnostic information may come from ascertaining which joint was first involved i e the proximal interphalangeal joint in rheumatoid arthritis the sacroiliac in rheumatoid spondylitis the

istal interphalangeal in degenerative joint disease the great toe in gout or the shoulder in bursitis One should find out whether the arthritis is *migratory* and if it is the *nature of its spread* In degenerative joint disease for example the sites of arthritic symptoms do not tend to change whereas migration of the arthritis is characteristic of rheumatic fever where it is rapid and transient and of rheumatoid arthritis where it tends to be slower and additive Rheumatoid arthritis is noted for the *symmetry* of involvement of joints

The *course* of the disease may provide additional diagnostic clues Acute exacerbations with complete remissions are characteristic of intermittent hydrarthrosis where the flare ups occur regularly and of the early stage of gout where they occur irregularly Over all progression with partial remissions is the most common course in rheumatoid arthritis whereas in degenerative joint disease the illness is usually static or slowly progressive

The presence and extent of *deformities* and the *functional capacity* of the patient may also aid in diagnosis Some disorders such as rheumatoid arthritis are notoriously deforming and crippling others such as rheumatic fever produce no residual articular disability

The details of *previous management and its effect* should be carefully recorded The daily dosage and duration of administration of a given agent are important for the program may not have been sufficient to constitute a valid therapeutic trial An illustration of the potential usefulness of knowing the previous response to therapy is in so called "psychogenic rheumatism" where the diagnosis is said to be confirmed by a reportedly complete lack of response to salicylates or physical therapy

Physical Examination All accessible joints should be systematically and meticulously examined for heat or discoloration of the overlying skin swelling tenderness limitation of motion deformity and crepitation The *temperature* and *color* of the skin proximal and distal to the joint should be compared with those over the joint *Swelling* of the joint may result from one or more of the following pathologic conditions (1) the accumulation within the joint space of fluid demonstrable by fluctuation as in the "patellar click" (2) thickening of the soft tissue (synovia capsule ligament or adipose tissue) in which case there is no fluctuation (3) localized periarticular effusion in a tendon sheath or a bursa (4) diffuse periarticular subcutaneous edema or (5) bony enlargement as in acromegaly tumors of bone or the osteophytes of degenerative joint disease One must be sure that the joint is really enlarged since atrophic muscles may falsely give the impression of joint swelling The degree of *tenderness* should be recorded and subsequently interpreted with the help of the sensory examination and an evaluation of the emotional state of the patient

Limitation of motion of a joint may result from (1) sufficiently painful inflammation to cause muscular spasm or guarding (2) effusions large enough to distend the capsule tightly (3) fibrosis of the capsule (4) fibrosis across the joint space from one synovial surface to another (fibrous ankylosis) (5) bony bridging across the space (bony ankylosis) or (6) various disorders of tendon muscle or nerve One should try to determine whether the *deformity* results from effusion or pain and thus is possibly reversible or from irreversible destruction of joint structures

Crepitation a grating feeling or noise results from the rubbing together of opposing joint surfaces on motion of the joint The character of the crepitation varies with the joint disorder fine or rubbing in rheumatoid arthritis where the abrasive surface is villous granulation tissue coarse or "crunching from the osteophytes and disorganized cartilage in degenerative joint disease These forms of crepitation should be distinguished from "cracking" or "snapping which is caused by slipping tendons over bony prominences

A few instruments are available for quantitating the degree of disability of joints and related structures Simplest and perhaps most important is a tape measure with which the circumference of large joints and certain muscle groups is recorded It should also be used to measure the chest expansion in patients with rheumatoid spondylitis A jeweler s ring sizer can determine the size of the smaller joints of the fingers and toes A dynamometer is used to record grip strength the range of motion of a joint can be ascertained with a goniometer These instruments are useful in following the course of the patient s illness and particularly in studies designed to test the efficacy of a therapeutic agent

The *functional capacity* of the patient with special reference to tasks performed by the extremities should also be carefully recorded Can the patient get out of bed walk or climb stairs? Can he comb his hair tie his shoelaces unscrew a bottle cap or sweep the floor?

Organs other than the joints which deserve special attention in the physical examination of the arthritic patient include the skin subcutaneous tissue eyes pharynx lymph nodes lungs heart liver spleen muscles and nerves

Valuable clues to the diagnosis of the joint disorder come from abnormalities of the *skin* Associated urticarial wheals point to serum sickness Petechiae and ecchymoses suggest meningococcemia

or a defect of blood coagulation a butterfly rash systemic lupus erythematosus and erythema marginatum rheumatic fever

The patient complaining of arthritis of the hands may exhibit no evidence of arthritis but rather diffuse swelling of the subcutaneous tissue as seen in the early stages of scleroderma *Subcutaneous nodules* are frequently encountered in patients with various forms of arthritis Those occurring on the extensor surfaces of the forearms just distal to the elbows are thought to be the hallmark of rheumatoid arthritis although sarcoid or lupus nodules or gouty tophi may occasionally occur in the same location A striking feature of the nodules of rheumatoid arthritis is their symmetry The nodules in rheumatic fever are more transitory less symmetrical softer and not so frequently near joints the distribution of those of polyarteritis nodosa and amyloidosis tends to be linear along the course of affected arteries The external ears should be carefully searched for gouty tophi Tophi or nodules near joints are usually fixed to the periosteum or the joint capsule Synovial cysts *ganglions* should not be mistaken for nodules or tophi

The ocular examination may yield useful information in differential diagnosis Conjunctivitis may suggest Reiter's syndrome keratitis gonococcal arthritis or Clutton's joints uveitis rheumatoid arthritis or sarcoid cytoid bodies systemic lupus erythematosus and retinal arterial thromboses polyarteritis nodosa

Similar differential diagnostic analyses can be constructed for the other extraarticular organs previously listed

Laboratory Tests After a careful history has been recorded and a thorough physical examination performed the aid of certain appropriate laboratory studies should be obtained The *hematologic examination* should be performed in all arthritic patients In rheumatoid arthritis rheumatic fever or sarcoid anemia may be mild or moderate in some patients with collagen vascular disease it may be more severe In rheumatoid arthritis the anemia is typically hypochromic and normocytic whereas in systemic lupus erythematosus it is usually normochromic and normocytic but may be hemolytic The white blood cell count is usually slightly elevated in serum sickness rheumatic fever many cases of active rheumatoid arthritis and some infectious arthritides it may be greatly elevated in other infections polyarteritis nodosa and leukemia Conversely leukopenia frequently accompanies tuberculous arthritis Felty's syndrome systemic lupus erythematosus and sarcoid In purpuric states the platelets should be counted and when indicated further special studies on blood coagulation performed

The erythrocyte *sedimentation rate* is one of the more important laboratory determinations in rheumatology It is particularly useful in (1) the differential diagnosis of the mild early case (2) estimating the severity of the inflammation in those conditions such as rheumatic fever or rheumatoid arthritis where the rate is known to be elevated and (3) determining by serial tests the course of the arthritis and the effect of therapy Among the disorders of joints the rate is usually high in infectious arthritis serum sickness acute phases of rheumatic fever rheumatoid arthritis and variants and collagen vascular disorders acute gouty arthritis and neoplasms in or near joints Normal values are recorded in degenerative joint disease traumatic arthritis neurogenic arthropathy fibrositis psychogenic rheumatism and between acute attacks of inflammatory or gouty arthritis The test is nonspecific A normal rate cannot be relied upon to rule out such diseases as rheumatic fever or rheumatoid arthritis because the disease may be only minimally active or there may have been technical difficulties In such cases the determination should be repeated Various nonspecific acute *phase reactions such as that to C reactive protein* may also help to estimate the activity of the arthritis

Other *serologic* tests may also aid in diagnosis One or more of the serologic tests for syphilis (STS) may not only indicate that the patient has one of the several rheumatic sequelae of this infection but also augment the physician's alertness to the possibility of gonococcal arthritis If the STS is positive a *Treponema pallidum* immobilization test (TPI) should also be performed since it has been shown that many patients with a false positive STS have some form of connective tissue disease The antistreptolysin O titers of serum help greatly to confirm the diagnosis of rheumatic fever being elevated in more than 85 per cent of patients with active polyarthritis caused by this disease

The sheep cell agglutination test is positive in approximately 75 per cent of patients with active peripheral rheumatoid arthritis unaccompanied by psoriasis or spondylitis and in over 90 per cent of patients with subcutaneous nodules It is not entirely specific for rheumatoid arthritis however and positive tests may be found in patients with systemic lupus erythematosus or progressive systemic sclerosis (scleroderma) Other serologic agglutination tests for brucellosis or tularemia or gonococcal complement fixation are occasionally useful

If possible *L E cell* preparations should also be made in arthritic patients especially those in whom the diagnosis is in doubt The importance of this test is readily grasped when one realizes that arthralgia or arthritis is the presenting manifestation

in one third of patients with systemic lupus erythematosus

Since the rheumatic manifestations of gout are so pleomorphic all patients with joint complaints should have a blood *uric acid* determination

Urinalysis and tests of renal function may help in difficult diagnostic situations by focusing one's attention on the possibilities of Reiter's syndrome gout one of the collagen vascular disorders or amyloidosis secondary to rheumatoid arthritis

X ray findings also aid materially when interpreted in the light of clinical and other laboratory information They should not be considered the final arbiter however since different types of arthritis may produce identical roentgenographic changes Furthermore even in obviously inflamed joints the x ray findings may be totally negative in the early stages of illness

Bacteriologic cytologic and chemical examination of *synovial fluid* may provide further information of diagnostic and prognostic importance The splendid monograph by Ropes and Bauer has done much to increase our knowledge of the characteristics of joint fluid both in normal persons and in those with various pathologic states

Normal synovial fluid is small in volume clear pale yellow sticky and relatively acellular It is essentially a dialysate of blood plasma the albumin passing through readily but the globulin passing through with difficulty The fluid which helps to lubricate the articulating surfaces contains mucin a protein polysaccharide complex similar to that found in the ground substance of connective tissue

A proper examination of joint fluid should include all those features recorded in the analysis of fluid from other body cavities i e volume appearance specific gravity reaction cell counts including a differential and concentrations of protein and sugar (with comparative blood levels) Anaerobic as well as aerobic cultures should be planted immediately A Gram stain of the centrifuged sediment should also be carried out If tuberculosis is suspected an aliquot of the fluid should be inoculated into a guinea pig The turbidity should be estimated and the fluid observed for clot formation The diluting medium for white cell counts should be physiologic saline and not acetic acid because the addition of acetic acid to normal joint fluid so precipitates or denatures the mucin that a ropy clot is formed An icteric index of the joint fluid may be helpful in cases where traumatic arthritis is suspected

Fluids obtained from patients with joint disorders fall into two antagonistic groups and there is a third group with *intermediate findings* Diseases included within the first group are degenerative joint disease traumatic arthritis neurogenic arthropathy osteochondromatosis and osteochondritis dissecans In these disorders the amount of fluid is usually increased but the changes from normal are small slightly more polymorphonuclear leukocytes slightly less mucin and therefore slightly reduced viscosity

The second group comprises all the specific infectious arthritides Reiter's syndrome rheumatoid arthritis and intermittent hydrarthrosis The aspirated fluids in this group appear turbid clot readily and have a low viscosity Although there is considerable variation the white cell count is elevated largely as a result of a polymorphonuclear response Sugar concentration is usually reduced and the protein concentration is elevated with a considerable contribution from the globulin fraction

Among the disorders which fall in the intermediate group the findings in systemic lupus erythematosus hemophilia and hypertrophic osteoarthropathy more closely resemble those in the first group those of the second are more frequently seen in the synovial fluids of rheumatic fever gout and synovial tumors

It is thus clear that in many situations where diagnosis is difficult such as between rheumatoid and gonococcal arthritis the solution may not be found by cytologic or chemical analysis of the synovial fluid On the other hand in many other situations as in the patient who has either a Charcot joint or gonococcal arthritis or others in whom the choice lies between traumatic or rheumatoid arthritis the diagnostic dilemma may be resolved by such an analysis

When all the above methods have failed to clarify the diagnostic problem a *biopsy* specimen of an affected joint may be obtained The value of the histologic method in the diagnosis of rheumatic disease however is somewhat limited by the paucity of accumulated experience not only in diseased joints but in normal ones as well This deficiency exists largely because in this country dissection of joint structures at post mortem examination is illegal unless special permission is obtained and joint biopsies have been performed infrequently In doing the latter procedure strict aseptic precautions should be observed A method of securing a punch biopsy of the synovial membrane of the knee has been introduced but its usefulness is limited as in punch biopsy of the liver by the small amount of tissue for examination This deficiency is significant in light of studies describing in several rheumatic disorders great variability in pathologic change from place to place in the same specimen Nevertheless synovial biopsy can answer various diagnostic problems by differentiating gout from rheumatoid arthritis (by revealing urate crystals) or rheumatoid from tuberculous arthritis (by demonstrating acid fast bacilli) More

over biopsy findings have added to our knowledge of the rheumatic diseases by showing for example that sarcoid or progressive systemic sclerosis (scleroderma) may involve the synovium as well as other more usual sites

RHEUMATOID ARTHRITIS

Definition Rheumatoid arthritis (atrophic arthritis chronic proliferative arthritis chronic infectious arthritis) is a systemic disease of unknown etiology in which symptoms and inflammatory change predominate in articular and related structures The course is extremely variable but tends to be chronic and to result in characteristic deformities There are several variant forms of this disease The relationship between these and the classical variety of peripheral rheumatoid arthritis is not clear hence they will be discussed separately

Epidemiology Accurate statistics relating to the prevalence of rheumatoid arthritis within the population at large or within any group of patients with rheumatic complaints as well as the prevalence of individual findings within the disease are not yet available since it cannot be defined closely or diagnosed with precision A large proportion of patients become incapacitated in one study 58 per cent were unable to carry out their ordinary occupations or duties

This malady is not limited to any *age* group It can begin in children nine months of age and in patients in the ninth decade In the United States the onset of the disease occurs most frequently in *the thirty to thirty nine year old group*

Most studies indicate that the disease occurs three times more commonly in women than in men This does not apply at all age groups for in older patients if more definite criteria such as x ray changes are used neither sex predominates There is no racial predisposition

There seems to be a *familial* tendency in rheumatoid arthritis One study concludes that this is the result not of common environmental factors but rather of a genetically determined susceptibility controlled by an autosomal dominant gene with 50 per cent penetrance

It is well established that rheumatoid arthritis is most prevalent in the Temperate Zones more specifically in areas with cold damp *climates* Many patients point with ironic pride to their ability to prognosticate the weather Although this may well be questioned the coincidence of cold damp weather with aggravation of arthritic symptoms is impressive Well controlled studies of the relationship between arthritic symptoms or objective evidence of arthritis and climatic variable have not been carried out

Pathology Rheumatoid arthritis is recognized pathologically by inflammatory changes more chronic than acute predominating in joint structures with a predilection for certain diarthrodial joints There is virtually no specificity to these changes per se and similar changes are seen in various other tissues of mesenchymal origin It is only by the fairly characteristic distribution of the lesions that the disease is discernible

The histologic changes observed depend on the stage and severity of the disease and on the chance selection of the tissue observed They include the usual changes of chronic inflammation edema proliferation of capillaries and fibroblasts and infiltration at first with round cells and a few polymorphonuclears and later with plasma cells This may progress further to the formation of granulation tissue and to fibrosis Within the granulation tissue one sees islands of fibrinoid change and necrosis

The consequences of these *joint changes* are the thickening of the synovial membrane destruction of cartilage and bone and ankylosis The thickening of the synovium assumes the form of villous hypertrophy and may be so extensive that the joint space widens At this stage lymphoid follicles and foci of fibrinoid change may be seen histologically Later the layer of granulation tissue called *pannus* begins to invade and destroy cartilage presumably by interfering with its proper nutrition The villi of the pannus may interdigitate with corresponding villi on the opposing pannus forming the nidus for fibrous adhesions and ankylosis Ossification may take place in these fibrous adhesions and bony *ankylosis ensues Subchondral granulation may* be so extensive that bony trabeculae may be resorbed Changes similar to those in the synovial membrane described above take place in the joint capsule tendon sheaths and bursae

Subcutaneous nodules are frequently located near tendon sheaths or bursae but may also be found distant from these structures Similar nodules are found in other organs of the body Histologically the nodules consist of clusters of granulation tissue in which foci of fibrinoid material and necrosis are surrounded by palisading (lining up) of inflammatory cells mostly mononuclear cells Whereas an old subcutaneous nodule is an avascular structure with central necrosis the young nodule consists of vascular granulation tissue the small arteries often undergoing active inflammatory change (arteritis)

In addition to atrophy and degeneration of *muscle* fibers which presumably are the consequences of disease nodular lymphocytic infiltrates *may be widely distributed* about blood vessels and between muscle fibers Similar lesions however are seen frequently in several other rheumatic dis

eases and indeed the infiltrate closely resembles the lymphorrhagia of myasthenia gravis

Cardiac lesions occur in different forms Healed pericarditis usually focal is seen in as many as 25 per cent of cases at necropsy Granulomatous lesions morphologically similar to those of the subcutaneous nodule are also found in the myocardium and the aortic and mitral valves Lesions indistinguishable from those of rheumatic heart disease are reported to occur in 19 to 60 per cent of autopsied cases of rheumatoid arthritis Although these percentages are probably excessive the relationship between the two diseases seems to be beyond the realm of chance

An *arteritis* then although not common may be found in synovial membrane subcutaneous nodule muscle heart and other organs It is of special interest because it constitutes a common link with the lesions of rheumatic fever and the collagen disorders (systemic lupus erythematosus progressive systemic sclerosis and polyarteritis nodosa)

Secondary *amyloidosis* commonly complicates rheumatoid arthritis occurring in as many as 20 per cent of severely disabled individuals at post mortem examination

Etiology Both the cause and the pathogenetic pathways of rheumatoid arthritis remain unknown Many hypotheses have been put forth only to be discarded because of a lack of convincing evidence

Exhibiting many of the characteristics of an inflammatory process—fever lymphadenopathy inflamed joints leukocytosis and an elevated sedimentation rate—rheumatoid arthritis was once considered to be almost unequivocally an *infectious* disease A few adherents of the "focus of infection" school persist in having their patients free of teeth tonsils and paranasal sinus mucosa Neither removal of the offending focus nor chemotherapy has altered the course of the disease and most patients do not appear to harbor such foci Attempts to transmit the disease via synovial fluid or by transplanting a rheumatoid nodule have failed

Perhaps the most widely held concept of the etiology of rheumatoid arthritis is that it is a disease of *hypersensitivity* This stems in great measure from the analogy drawn between it and rheumatic fever

Some have described a personality structure peculiar to patients with rheumatoid arthritis Convincing evidence that psychologic aberrations initiate the disease is not available

After Hench revealed the beneficial effects of ACTH and cortisone the inference was drawn by many that patients with rheumatoid arthritis were *adrenocortically deficient* However steroid studies on blood and urine reveal normal or slightly low levels in rheumatoid arthritis as in any other chronic illnesses The coincidence of rheumatoid arthritis and Addison's disease is rare Moreover steroid doses required for the alleviation of symptoms in rheumatoids are much higher than those used for replacement therapy in Addison's disease Most investigators agree that steroid therapy in rheumatoid arthritis is pharmacologic and exerts an anti inflammatory action

So we end where we began cause unknown A variety of noxious stimuli can make the disease worse but which if any of these is important initially? More intensive study of the early acute arthritic whether he turns out to have rheumatoid arthritis or not is sorely needed

Clinical Features The over all clinical picture in rheumatoid disease is highly variable with respect to (1) the number of organ systems involved (2) the severity of the involvement and (3) the course of the disease In some patients the illness may be acute and fulminating with appreciable fever signs of intense joint inflammation and the rapid evolution of severe deformities in others mild deformities may develop insidiously and with little discomfort to the patient

The earliest symptoms are frequently not articular but constitutional namely fatigability anorexia and weight loss At this stage many patients complain of paresthesias or numbness of the hands and feet Others begin to notice evanescent aches and pains in muscles and joints It deserves emphasis that these prodromal constitutional symptoms may antedate the onset of arthritis by several months or years

The great majority of patients seek the help of the physician only after the manifestations of joint inflammation—pain swelling redness heat or deformity—have appeared Although virtually any joint in the body may be involved first the metacarpophalangeal and proximal interphalangeal joints of the hands seem to be the most common sites of initial attack The wrists knees ankles and feet are also frequently involved early in the disease In some elderly patients however the disease may first appear atypically in the shoulders or hips and an erroneous diagnosis of degenerative joint disease is often made Rheumatoid arthritis is characteristically a migratory polyarthritis In the representative case the disease migrates from one joint to another at a moderate speed (in most cases much more slowly than in rheumatic fever) Once affected a joint tends to remain inflamed for weeks months or even years Symmetry of joint involvement is an intriguing common feature Tenosynovitis is occasionally seen in rheumatoid arthritis but suggests more strongly gonococcal arthritis Joint deformities are caused by intrinsic articular disease shortening of tendons and the muscle imbalance which results from involuntary splinting (muscle spasm) about an inflamed joint or from inflamma

tory changes in the muscle as part of the rheumatoid process Deformities usually assume the form of flexion contractures Favorite sites for flexion deformities include the metacarpophalangeals wrists elbows and knees Ulnar deviation is a very common deformity and constitutes one of the hallmarks of rheumatoid arthritis Advancing disease also gives rise to various subluxations and ankylosis

The *skin* especially over the extremities and more so distally is cool pale and clammy Excessive sweating of the palms and soles is characteristic Over the fingers the skin appears taut and shiny and erythema of the hypothenar eminences identical with liver palms is a common finding Fleeting erythematous blotches may be present on other areas Purpuric eruptions over the extremities are infrequent There may be hyperpigmentation especially over the joint surfaces

Subcutaneous nodules are found in 10 to 20 per cent of patients with rheumatoid arthritis They are firm nontender round or ovoid masses varying from 2 mm to 2 cm in diameter The overlying skin slides over them easily and they may or may not be attached to underlying structures They are located usually over pressure points and near bones and joints The most common site is the extensor surface of the forearm just below the elbow In the bedridden patient they may appear over the scapulae or the buttocks In general patients with nodules have active and severe disease Nodules are rare in juvenile rheumatoid arthritis ankylosing spondylitis or psoriatic arthropathy Characteristically the nodules persist for months or years Typical rheumatoid nodules both clinically and histologically have also been found in patients with systemic lupus erythematosus thus casting some doubt on the dictum that the subcutaneous nodule is the hallmark of rheumatoid arthritis Moreover the nodules of many other diseases (gout sarcoid xanthomatosis syphilis etc) may clinically closely resemble those of rheumatoid arthritis

Muscle symptoms—aching tenderness and stiffness—may occur early in rheumatoid arthritis as has been stated and are prominent throughout the course of the disease Morning stiffness and stiffness after inactivity are common complaints Muscular atrophy and weakness may be striking To what extent these changes in muscle are due to direct inflammatory disease disuse or reflex aberrations is not known Attempts to demonstrate electromyographic changes indicative of muscle spasm have failed Increased urinary creatine excretion has been recorded in some bedridden patients with severe muscle wasting

Among the various *ocular lesions* in rheumatoid arthritis perhaps the most common is an anterior nongranulomatous usually bilateral uveitis occurring in approximately 2 per cent of cases Episcleritis and scleritis may also appear either as a nonspecific inflammation or as nodules which are histologically similar to the rheumatoid subcutaneous nodule In rare instances such nodules may perforate the sclera and thus cause extrusion of the uveal tract this condition is called *scleromalacia perforans*

During active phases of the disease the *lymph nodes* may be prominently enlarged In the striking case the patient is often thought to have a lymphomatous disease

Clinical manifestations of *heart* disease probably do not occur more frequently in patients with rheumatoid arthritis than in the general population Such a view contrasts sharply with the high incidence of cardiac lesions—granulomatous and fibrotic—reported in post mortem material

Laboratory Findings A mild or moderate *anemia* may be found in active rheumatoid arthritis It is usually normocytic and slightly hypochromic The anemia does not usually respond to iron therapy and never to folic acid or vitamin B_1 Transfusions are rarely indicated Splenectomy is ineffective

The *white cell* count is within normal limits in 80 per cent of cases A mild leukocytosis is common in early active disease In chronic long standing cases there may be a slight leukopenia

The erythrocyte *sedimentation rate* is almost always elevated during active disease and it is valuable as a rough index of activity Other nonspecific host responses which may be used to estimate disease activity include the presence of C reactive protein hypoalbuminemia hyperglobulinemia with elevations predominantly in the alpha 2 and gamma fractions and positive cephalin cholesterol flocculation

Other *serologic reactions* do not correlate well with disease activity and persist in the face of a spontaneous remission or one induced by adrenocortical steroid therapy These include the sheep cell agglutination tests and the agglutination of group A hemolytic streptococci The latter is technically difficult and thus impractical for routine clinical application The sheep cell test is undergoing widespread intensive investigation It is positive in 75 per cent of patients with active peripheral rheumatoid arthritis and in over 90 per cent of patients with subcutaneous nodules The incidence of positive tests is much lower however in the early stages of the disease when it would be most helpful in differential diagnosis Positive tests are found less frequently in juvenile rheumatoid arthritis ankylosing spondylitis and arthritis with psoriasis The specificity of the test for rheumatoid arthritis has been questioned since positive tests are not uncommonly obtained in patients with systemic lupus erythematosus or progressive systemic sclerosis

Both 17 ketosteroids and 11 oxysteroids in the urine are usually within the normal range but occasionally may be decreased as they are in several other chronic illnesses

Synovial fluid findings discussed previously are usually not specific

Roentgen findings in rheumatoid arthritis are less helpful than is generally realized In the face of obvious active inflammation no roentgen abnormalities may be found even after several months This is because the primary pathology resides in the synovial membrane In most patients however at least one radiologic abnormality usually appears within the first 6 months One sees evidence of soft tissue swelling about the affected joints the result of chronic periarticular inflammation At any stage of the disease and often early there may be osteoporosis which first appears in the areas adjacent to the involved joints and later becomes generalized Generalized osteoporosis is more likely to occur in patients on prolonged bed rest and not undergoing physiotherapy As the disease progresses and the articular cartilage becomes destroyed the joint space becomes narrower still later with fibrous or bony ankylosis it may be obliterated and subluxations may be seen

Diagnosis In the patient who gives a history of prodromal symptoms paresthesias weight loss repeated episodes of acute migratory polyarthritis and who exhibits on examination symmetrical deforming arthritis with flexion contractures ulnar deviation and subcutaneous nodules a diagnosis of rheumatoid arthritis may be readily made However the help of a physician is usually sought at an earlier stage of the disease when the clinical picture may be that of an acute febrile polyarthritis or merely monarticular disease There is no single pathognomonic feature to be sought from the history or physical examination nor is there a specific diagnostic laboratory test

There are many syndromes which may mimic rheumatoid arthritis in its early phases One of these is *rheumatic fever* (p 859) which may be differentiated from rheumatoid arthritis in its acute polyarticular form by the history of an antecedent upper respiratory tract infection an elevated antistreptolysin O titer (although elevations are found in 20 per cent of patients with rheumatoid arthritis) evidence of carditis and the dramatic response of the arthritis to salicylates (although the response is occasionally striking in rheumatoid arthritis) Another is *systemic lupus erythematosus* (p 1700) in which arthritis or arthralgia occurs in 90 per cent of cases at some time during the course appears to be typical rheumatoid with deformities in one fourth of the cases and in one third constitutes the initial manifestation of illness With the passage of time the additional involvement of the skin kidneys pleura lungs peritoneum or central nervous system as well as certain hematologic abnormalities such as leukopenia thrombocytopenia and hemolytic anemia and the demonstration of L E cells lead to the diagnosis of systemic lupus erythematosus An acute attack of *gout may* closely resemble early rheumatoid arthritis but may be ruled out by a normal blood uric acid concentration and more conclusively by a failure to respond promptly to colchicine *Gonococcal arthritis* can be differentiated from rheumatoid disease by the demonstration of the microorganism a favorable response to penicillin and perhaps by the complement fixation test In the patients with proved venereal gonococcal infection but sterile synovial fluid a failure to respond to penicillin and prolonged polyarthritis the syndrome is thought by some to be a distinct disease entity Others think it is rheumatoid arthritis triggered by the gonococcal infection

Degenerative joint disease is distinguished from rheumatoid arthritis by the presence of Heberden s nodes the involvement of the distal rather than the proximal interphalangeal joints the extraordinarily infrequent involvement of the metacarpophalangeal joints and the lack of muscular wasting It is also distinguished by a normal erythrocyte sedimentation rate and no anemia and roentgenographically by the presence of osteophytes and the absence of osteoporosis and ankylosis

In the last analysis one of the chief diagnostic aids in rheumatoid arthritis is the passage of sufficient time to observe the course of the disease

Management The term management" is used to emphasize that there is no known cure for rheumatoid arthritis and that proper care should be comprehensive including various measures in addition to the administration of drugs Efforts are directed toward (1) the proper amounts of rest and exercise (2) the relief of pain (3) combating the rheumatoid process (4) preventing deformities (5) correcting deformities which have developed (6) controlling the complications of the disease (7) maintaining adequate nutrition and (8) rehabilitating the patient Of these the greatest need as yet unfulfilled is for reliable methods of arresting the disease process itself

It is generally agreed that the earlier the therapeutic efforts the more salutary the outcome The patient should develop a degree of optimism and confidence but should under no circumstances expect a rapid cure He should be told that although much can be done to relieve pain and prevent crippling the course of his disease cannot be predicted with precision and medical care may be required over months or even years It is also generally agreed that a variety of unfavorable stimuli such as physical injuries infections or emotionally

tory changes in the muscle as part of the rheumatoid process Deformities usually assume the form of flexion contractures Favorite sites for flexion deformities include the metacarpophalangeals wrists elbows and knees Ulnar deviation is a very common deformity and constitutes one of the hallmarks of rheumatoid arthritis Advancing disease also gives rise to various subluxations and ankylosis

The *skin* especially over the extremities and more so distally is cool pale and clammy Excessive sweating of the palms and soles is characteristic Over the fingers the skin appears taut and shiny and erythema of the hypothenar eminences identical with liver palms is a common finding Fleeting erythematous blotches may be present on other areas Purpuric eruptions over the extremities are infrequent There may be hyperpigmentation especially over the joint surfaces

Subcutaneous nodules are found in 10 to 20 per cent of patients with rheumatoid arthritis They are firm nontender round or ovoid masses varying from 2 mm to 2 cm in diameter The overlying skin slides over them easily and they may or may not be attached to underlying structures They are located usually over pressure points and near bones and joints The most common site is the extensor surface of the forearm just below the elbow In the bedridden patient they may appear over the scapulae or the buttocks In general patients with nodules have active and severe disease Nodules are rare in juvenile rheumatoid arthritis ankylosing spondylitis or psoriatic arthropathy Characteristically the nodules persist for months or years Typical rheumatoid nodules both clinically and histologically have also been found in patients with systemic lupus erythematosus thus casting some doubt on the dictum that the subcutaneous nodule is the hallmark of rheumatoid arthritis Moreover the nodules of many other diseases (gout sarcoid xanthomatosis syphilis etc) may clinically closely resemble those of rheumatoid arthritis

Muscle symptoms—aching tenderness and stiffness—may occur early in rheumatoid arthritis as has been stated and are prominent throughout the course of the disease Morning stiffness and stiffness after inactivity are common complaints Muscular atrophy and weakness may be striking To what extent these changes in muscle are due to direct inflammatory disease disuse or reflex aberrations is not known Attempts to demonstrate electromyographic changes indicative of muscle spasm have failed Increased urinary creatine excretion has been recorded in some bedridden patients with severe muscle wasting

During active phases of the disease the *lymph nodes* may be prominently enlarged In the striking case the patient is often thought to have a lymphomatous disease

Clinical manifestations of *heart* disease probably do not occur more frequently in patients with rheumatoid arthritis than in the general population Such a view contrasts sharply with the high incidence of cardiac lesions—granulomatous and fibrotic—reported in post mortem material

Laboratory Findings A mild or moderate *anemia* may be found in active rheumatoid arthritis It is usually normocytic and slightly hypochromic The anemia does not usually respond to iron therapy and never to folic acid or vitamin B_1 Transfusions are rarely indicated Splenectomy is ineffective

The *white cell* count is within normal limits in 80 per cent of cases A mild leukocytosis is common in early active disease In chronic long standing cases there may be a slight leukopenia

The erythrocyte *sedimentation rate* is almost always elevated during active disease and it is valuable as a rough index of activity Other nonspecific host responses which may be used to estimate disease activity include the presence of C reactive protein hypoalbuminemia hyperglobulinemia with elevations predominantly in the alpha 2 and gamma fractions and positive cephalin cholesterol flocculation

Other *serologic reactions* do not correlate well with disease activity and persist in the face of a spontaneous remission or one induced by adrenocortical steroid therapy These include the sheep cell agglutination tests and the agglutination of group A hemolytic streptococci The latter is technically difficult and thus impractical for routine clinical application The sheep cell test is undergoing widespread intensive investigation It is positive in 75 per cent of patients with active peripheral rheumatoid arthritis and in over 90 per cent of patients with subcutaneous nodules The incidence of positive tests is much lower however in the early stages of the disease when it would be most helpful in differential diagnosis Positive tests are found less frequently in juvenile rheumatoid arthritis ankylosing spondylitis and arthritis with psoriasis The specificity of the test for rheumatoid arthritis has been questioned since positive tests are not uncommonly obtained in patients with systemic lupus erythematosus or progressive systemic sclerosis

order to attain maximal effectiveness the initial dose should be 200 mg three or four times daily Because of the serious side reactions lower doses 300 to 400 mg daily are now recommended but hematopoietic difficulties have occurred even at this lower dosage In view of the toxicity of phenylbutazone it should not be given until after other less hazardous measures have failed it is contraindicated in patients with a history of allergy peptic ulcer or cardiovascular renal disease If after 7 to 10 days of administration the patient does not improve the drug should be discontinued

Adrenocortical Hormones A full and detailed discussion of adrenocortical steroid therapy in clinical medicine including the various types of steroid hormones dosage route of administration contraindications complications and precautions appears elsewhere (p 596) In 1949 when Hench and his associates first demonstrated the prompt and striking subjective improvement in patients with active rheumatoid arthritis given cortisone or corticotropin there immediately emerged high hopes It was not long however before the limitations and dangers of these agents began to be recognized Considerable disagreement prevails upon such issues as whether or not they should be used at all in rheumatoid arthritis when to administer them which of the many steroids to select in what doses for how long and in conjunction with what other therapeutic measures

After several years of experience with these agents certain general conclusions may be drawn (1) Cortisone which is singled out for purposes of this discussion is a potent nonspecific antiinflammatory agent It does not act in rheumatoid arthritis as replacement therapy in a deficiency state as insulin does in diabetes mellitus (2) In the vast majority of patients with active rheumatoid disease cortisone in adequate dosage can induce rapid suppression of the symptoms and signs as shown by regression of fever joint manifestations size of enlarged lymph nodes scleral nodules and other signs of ocular inflammation and pericarditis Synovial fluid findings may revert to or toward normal (3) On the other hand in the face of clinical improvement anemia may not be completely corrected the erythrocyte sedimentation rate may not be reduced to normal levels the serum protein abnormalities may persist and the sheep cell agglutinating titer remain unaltered None of these tests should in itself serve as a guide to therapy (4) The results of cortisone treatment are better in earlier and milder cases Some beneficial results might well have occurred spontaneously Other variables important in the outcome are dose and duration of cortisone administration other concomitant therapeutic efforts and psychologic factors (5) Some patients fail to improve In many instances this may be attributed to irreversible changes severe contractures or ankylosis which had taken place prior to therapy or to insufficient dosage (6) Subjective and functional improvement usually exceed objective improvement. Joint destruction as shown by serial roentgenographic studies usually progresses (7) Cortisone therapy by itself is insufficient and should be combined with the usual conservative program—rest, physical therapy and salicylates Actually cortisone has proved an exceedingly helpful adjunct to both physical therapy and orthopedic surgical correction

It should be strongly emphasized that cortisone is hazardous and should be withheld until the fullest possible trial with rest, physical therapy and salicylates regularly given has failed to modify the course of the disease Nevertheless the concept that cortisone therapy should be a measure of last resort can be carried too far Time is important in rheumatoid arthritis the patient should not be allowed to become irreversibly incapacitated by his disease before cortisone is tried Rapidly progressing disease intractable pain requiring narcotics for control, and the patient s economic and social situation should also play a role in deciding when to institute steroid therapy

It is not agreed what the starting dose should be Some workers start with rather high doses in order to produce maximal benefits and to be able also to discern as early and clearly as possible whether improvement is being gained thus they are able to decide whether or not this form of therapy is worthwhile Others contend and this is the more common view that in such a chronic disease long term therapy will probably be required hence one should start with a lower safer dose 75 to 100 mg or less cortisone daily Whatever the initial dose after maximal improvement has taken place the dose is gradually reduced in a stepwise manner until significant symptoms and signs reappear at which point the dose may then be maintained for weeks or months Since experience has shown that such a maintenance dose is frequently accompanied by a high incidence of serious side reactions many workers have compromised their therapeutic efforts by being satisfied with that dosage level at which minimal side reactions occur This is called the *suboptimal dose* Usually a compromise is reached at levels ranging from 37.5 to 75 mg cortisone daily

Another problem is when to begin withdrawal of cortisone in the hope that the patient may be entering a remission spontaneously As yet there are no means of predicting such a remission However dose reduction should be carried out periodically at least every 6 months Whenever possible it is wise to resist the temptation of re treatment be-

disturbing situations may incite flare ups in the disease Thus a comprehensive approach to the patient is paramount At each visit the physician must allow sufficient time for a complete inventory of the patient s status

Evaluation of the efficacy of any therapeutic agent or method in rheumatoid arthritis is fraught with difficulties The variable and protracted nature of the disease calls for long term observations before meaningful data are obtained There is insufficient agreement on the criteria of improvement whether subjective objective or functional and the definition of a remission Many studies have been hampered by the lack of precise and uniform methods for measuring objectively the severity of disease activity by poor standardization of cases and by failure to include placebo controls The American Rheumatism Association has set up therapeutic criteria based entirely on objective evidence A functional classification is being more widely used and there is a growing tendency to use various devices for objective measurement in therapeutic trials

For the optimal care of patients with rheumatoid arthritis close cooperation between the internist orthopedic surgeon physiatrist and social worker is essential

Rest and Exercise Most agree that in certain stages of rheumatoid arthritis rest is beneficial In general patients with acute polyarthritis and fever should be at complete bed rest In milder cases 8 to 10 hr at night and brief rest periods during the day should be advised Excessive fatigue should be avoided In order to maintain the patient s morale he should be encouraged to continue work as long as it is not tiring or traumatizing to joints In mild and moderate cases special exercises should be prescribed along with rest to obtain the fullest possible range of joint motion but these should not be so severe that joint pains persist for more than 1 hr thereafter During the periods of severe disease and especially in the early case hospitalization is highly desirable to establish the optimal medical regimen and to institute and instruct the patient in the physiotherapy which he is to continue at home

Relief of Pain Pain relief is important in itself and must be achieved before active physical therapy can be undertaken Many of the physical measures to be described such as the application of heat may help to alleviate pain Drugs such as morphine and Demerol and the like should be strictly avoided because of the danger of addiction Codeine may be used in unusual circumstances for brief periods Since pain is largely the result of inflammation the drug of choice should be anti inflammatory rather than strictly analgesic Three widely used groups of agents help to combat inflammation salicylates phenylbutazone (Butazolidin) or its analogues and adrenocortical steroids in order of increasing potency The choice of one of these agents is conditioned not only by its anti inflammatory activity but also in a very serious way by its relative toxicity

Salicylates should be tried first because they frequently achieve the desired result are least toxic and least costly Acetylsalicylic acid (aspirin) and sodium salicylate seem to be equally effective but care should be taken not to give sodium salicylate to patients with cardiac or renal disease in whom sodium restriction is desired Aspirin should not be given only as needed for pain but regularly and frequently "around the clock in doses to maximal benefit or to tolerance Administration with meals and at bedtime often suffices Gastric disturbances may be overcome by using buffered aspirin or an enteric coated preparation The buffered form may cause distressing constipation The coated tablets sometimes traverse the gastrointestinal tract unaltered

The initial dose of aspirin in ambulatory patients is usually 2 4 Gm daily but if the response is unsatisfactory this should be raised in a stepwise manner until the desired response is achieved or side reactions supervene

Salicylate therapy should be given the fullest possible trial before turning to other agents In those cases not alleviated by salicylates there is considerable disagreement as to whether one should try gold therapy adrenocortical steroid therapy or phenylbutazone A few would give none of these three agents

Phenylbutazone (Butazolidin) has had wide spread clinical trial in various rheumatic states Curiously its effectiveness in rheumatoid spondylitis and acute gouty arthritis seems to be more striking and more predictable than in peripheral rheumatoid arthritis where among various groups major clinical improvement has been reported in approximately 25 per cent of cases The mechanism of its action has not been elucidated although it is said to be anti inflammatory The erythrocyte sedimentation rate does not decrease consistently with its administration Moreover it is potentially dangerous The incidence of side reactions varies considerably In one large series of 800 cases they appeared in 40 per cent of cases and in 15 per cent the drug had to be discontinued A number of fatalities have been attributed to these toxic effects which include serious hematopoietic disturbances such as agranulocytosis hypoplastic or hemolytic anemia and thrombocytopenia peptic ulceration at times with massive bleeding or perforation and retention of sodium and water It is stated that in

ness in the management of rheumatoid arthritis Massage to acutely inflamed joints may be harmful

Occupational therapy is extremely valuable in its own right psychologically and also as a form of exercise particularly of the upper extremities Physiatrists furthermore have developed a wide variety of devices and gadgets such as a long handled comb zippered shoes etc which increase the functional capacity of the crippled patient

Correction of Deformities Although a full discussion of the many methods which have been proposed for correcting joint deformities is beyond the scope of this textbook a few general comments seem worthwhile Stretching exercises usually accomplish little Manipulation of severely involved joints under anesthesia or wedging casts may do more harm than good Various promising surgical procedures for the correction of deformities have been described but need further evaluation

VARIANTS OF RHEUMATOID ARTHRITIS

Juvenile Rheumatoid Arthritis

Commonly called *Still's disease* this disorder begins in children before puberty The earliest reported age of onset is four months Contrary to a generally held view of its rarity a reliable estimate indicates that juveniles comprise 4 per cent of all rheumatoid patients

There are certain differences between the juvenile and adult forms of rheumatoid arthritis Systemic symptoms and signs are more severe in the juvenile Fever often reaches 105 F or higher and may last for months Lymphadenopathy occurs in 60 per cent of cases and splenomegaly in 30 per cent A transient and recurrent rash consisting usually of small erythematous macular or maculopapular lesions is seen in one fourth of cases Larger lesions which occur less frequently are characteristically scaling marginally red and raised and clear centrally Carditis (particularly pericarditis) pleuritis and pneumonitis are common features Subcutaneous nodules are rare The juvenile form tends to affect the larger joints especially in the earlier stages Spondylitis is common The distal interphalangeal joints are more frequently involved than in adult rheumatoid arthritis Impairment of growth and development may take place Leukocytosis is the rule and may be as high as 50 000 per cubic millimeter Sheep cell and similar agglutination reactions are usually negative

Early in the disease differentiation from acute rheumatic fever or systemic lupus erythematosus may be difficult When it presents monarticularly as in the hip or the knee tuberculous arthritis must be carefully ruled out

The natural history of juvenile rheumatoid arthritis has not been fully charted Contrary to earlier beliefs the disease may be mild and result in little deformity Satisfactory functional recovery occurs in three fourths of the patients Also contrary to earlier tenets the disease process does not terminate with puberty In cases with prolonged and severe involvement secondary amyloidosis may appear Management is generally similar to that for adult rheumatoid arthritis Attention should be directed toward the prevention of deformities

Rheumatoid Spondylitis

This disorder (also called *Marie Strumpell arthritis* or *ankylosing spondylitis*) is a chronic arthritis involving the spine sacroiliac joints and in a minority of cases peripheral joints as well Some investigators believe it to be a variant of rheumatoid arthritis and others think it is a separate and distinct but homogeneous disease Still others look on it as a heterogeneous group of diseases with a common symptomatology Those who propose that it is merely a variant point to the pathologic similarities in the two diseases and the fact that involvement of the peripheral joints in spondylitis is clinically indistinguishable from classical rheumatoid arthritis The separatists can marshal several supporting arguments Eighty to 90 per cent of spondylitics are men whereas 60 to 70 per cent of rheumatoids are women Spondylitis usually begins at a younger age Subcutaneous nodules are almost never found in spondylitis When the peripheral joints are involved in spondylitis the common sites are the large central joints—shoulders hips knees in rheumatoid arthritis fingers wrists toes and ankles predominate Serologic reactions such as sheep cell agglutination are usually negative in spondylitis Other perhaps less cogent points include the tendency for spondylitis to produce calcification of ligaments (absent in rheumatoid arthritis) to respond to x ray therapy and to fail to respond to gold Lastly the role of inheritance has been more firmly established in spondylitis It has occurred in identical twins and is apparently inherited through an autosomal dominant gene with a penetrance of 70 per cent for the male and 10 per cent for the female Others notably certain English investigators divide spondylitics into those who respond to x ray therapy and those in whom radiotherapy is ineffective Among the latter they report a high incidence of peripheral rheumatoid arthritis rheumatic fever Reiter's disease and psoriasis

The basic pathologic lesion is a *synovitis* similar to that of peripheral rheumatoid arthritis The disease usually begins in the sacroiliac joints Initially these exhibit condensation of bone later they show punched-out areas articular narrowing and in most instances obliteration of the joint space with bony ankylosis The next event is involvement

cause many exacerbations are temporary (less than 1 month)

The complications of cortisone administration and the contraindications to such therapy are discussed on p 596

Chrysotherapy Until the advent of adrenocortical steroid therapy gold compounds were perhaps the most popular of the specific agents in the treatment of rheumatoid arthritis Their use is highly controversial In spite of more than 9 000 reported cases a critical evaluation of the efficacy of gold in rheumatoid arthritis is almost impossible because of the paucity of well controlled clinical trials Several highly judicious investigators feel strongly that of all forms of therapy for rheumatoid arthritis gold compounds afford the greatest chance of inducing a remission Others believe these agents to be totally ineffective and still others are on the fence

The mechanism of action of gold compounds has not been elucidated They are not effective in any other rheumatic disease Conservative management should be tried before resorting to gold Many patients with sustained disease have entered into a remission coincident with the administration of gold As with other agents the results are usually most impressive in patients during the earlier stages of the disease Significant improvement usually takes place in 40 to 60 per cent of cases among the reported series In several centers conservative management consisting of rest corrective exercises and other physical therapy psychotherapy and salicylates is followed by significant improvement in approximately 50 per cent of cases A few well controlled clinical trials with small numbers of cases indicate little if any advantage for gold and long term studies show no difference in the end results between gold treated patients and those managed by more routine measures Gold is given over several weeks and the reported improvement characteristically occurs gradually The remissions seen after a single course are usually temporary The value of maintenance therapy has not yet been fully determined

Several gold compounds are available most contain approximately 50 per cent of metallic gold and are given intramuscularly The usual regimen consists of an initial test dose of 10 mg a second injection of 25 mg 1 week later and 50 mg weekly thereafter until a total dose of 1 0 Gm has been given Maintenance therapy is usually 50 mg every second or third week

Toxic reactions occur frequently (in up to 40 per cent of cases) vary in severity and are rarely fatal (probably less than 1 per cent) They include skin disorders varying from pruritus to severe exfoliative dermatitis stomatitis hematopoietic disturbances—hypoplastic anemia agranulocytosis or thrombocytopenia—and nephritis With the exception of the hematopoietic damage which may not respond to any form of therapy these toxic reactions usually disappear after gold is discontinued or if severe during treatment with BAL (British anti lewisite) or adrenocortical steroids Prior to each injection the patient should be carefully interviewed and examined for symptoms and signs suggesting gold toxicity There is neither synergism nor antagonism between gold and adrenocortical steroids

Physical Therapy In spite of the emergence of agents which alleviate pain or suppress inflammation physical therapy still remains important in the management of patients with rheumatoid arthritis The overriding principle of such therapy is the maintenance of maximal function by the preservation of normal joint motion and muscle strength

The proper positioning of the patient in bed is essential in preventing postural deformities A bed board should be placed under a firm mattress The pillow under the head should be small in order to combat the tendency towards dorsal kyphosis and flexion contracture of the hips Pillows should not be placed under the knees because they promote flexion contractures

The exercise regimen prescribed for the individual patient depends obviously on the severity of his disease In the severely ill bedridden patient exercises may be confined to passive maximal range of motion at least once daily When the disease becomes less active and joint pain is reduced active exercises may be started These should be done deliberately and slowly and their numbers increased gradually at each of three sessions daily Exercises are best carried out in a warm environment and preferably in a pool Stretching exercises may be helpful if performed conscientiously

Although rest splints are recommended in virtually all the standard writings their value has not been firmly established and their usefulness is limited by practical considerations General opinion is that gutter splints of the legs help to keep knee and ankle deformities to a minimum whereas splints applied to the wrists and fingers may not be successful Patients often complain that such splints are unsightly and burdensome they frequently stop wearing them after a few weeks

Heat locally or generally applied alleviates pain and muscular spasm thus permitting greater range of joint motion Consequently the heat is best administered immediately prior to exercise Locally hot moist compresses may be applied to one or two involved joints usually for 30 min Hot paraffin baths for the hands are especially useful because the heat is retained during exercise Complex devices such as whirlpool baths infrared lamps diathermy or ultrasonics have no special useful

respond to adrenocortical steroid therapy as in typical rheumatoid disease

Felty's Syndrome

In 1924 Felty reported a series of five patients with febrile migratory polyarthritis splenomegaly and leukopenia Subsequently many other such cases have been described and the disease presenting with this triad has since borne his name Three of his five patients also exhibited brown hyperpigmentation over the exposed surfaces Although this disease picture is considered by many to be merely a variant of rheumatoid arthritis it is possible that some of the patients may have rheumatoid arthritis and an unassociated hypersplenism Others may have systemic lupus erythematosus As a distinct clinical entity Felty's syndrome will probably not survive

Arthritis and Ulcerative Colitis

A very small proportion of patients with rheumatoid arthritis develop ulcerative colitis However a much larger proportion (ranging from 4 to 20 per cent) of patients with ulcerative colitis have arthritic symptoms (see p 1461) There are no objective articular signs in more than half of these but in the remainder the changes are those of typical rheumatoid arthritis In most patients the colitis is chronic and severe There is little correlation between the activity of the colitis and that of the arthritis After total colectomy arthritic symptoms may persist This disease must be carefully differentiated from the arthritis complicating cases of bacillary dysentery

Sjogren's Disease

This relatively rare condition of unknown cause otherwise known as *keratoconjunctivitis sicca* comprises dryness of the eyes nose mouth and pharynx in some cases enlargement of the lacrimal and parotid glands (see p 1085) achlorhydria and in approximately 80 per cent of cases joint changes characteristic of rheumatoid arthritis It is found mostly in middle aged and elderly females Interestingly a controlled study has indicated that one third of patients with rheumatoid arthritis have a deficiency of lacrimal secretion Management of the arthritis of Sjogren's disease is the same as that of rheumatoid arthritis

DEGENERATIVE JOINT DISEASE

Definition Degenerative joint disease (DJD) otherwise known as osteoarthritis hypertrophic arthritis or senescent arthritis is a chronic disorder characterized pathologically by degeneration of articular cartilage and hypertrophy of bone clinically by pain which appears with use and subsides with rest and by typical roentgenographic findings It occurs more commonly in older people usually affects the weight bearing joints and curiously the distal interphalangeal joints of the fingers It may develop spontaneously with advancing age (primary osteoarthritis) or at an earlier age as a sequel to articular injury of various kinds (secondary osteoarthritis) The pathologic changes may begin early in life and increase in frequency with each successive decade Pathologic joint changes may not give rise to articular symptoms There are no systemic manifestations as in rheumatoid arthritis

Epidemiology Degenerative joint disease is world wide although it is best known in temperate climates reflecting perhaps the longer life span of the populations in these areas It is an ancient disease In human beings it dates back to Neanderthal man (40 000 B C) It is also known to have afflicted prehistoric animals and changes identical with those in man may be found in a variety of present day animal species

Roentgenographic abnormalities usually do not appear until the third or fourth decade but after the age of fifty virtually everyone has some characteristic x ray changes Nevertheless only a minority experience symptoms Although this disorder is not so disabling as rheumatoid arthritis it has economic importance as revealed by the results of an industrial survey which showed that 14 per cent of all patients exhibiting objective evidence of musculoskeletal disease had degenerative joint disease It is largely a disorder of middle and late life often appearing in women at the time of the menopause Most studies reveal that DJD is divided equally between the sexes although for a variety of reasons (occupational genetic etc) the distribution of joint involvement does differ between them

Etiology Despite the antiquity of this disease only lately have we begun to gain an understanding of its pathogenesis and many questions still remain unanswered It is generally held that DJD is related to the physiologic process of aging Many anatomic studies including the excellent one of Bennett Waine and Bauer in which knee joints from persons one month to ninety years of age were examined reveal that alterations in the articular cartilage characteristic of DJD begin to appear as early as the second decade of life and increase in frequency and severity with advancing age The cause of these degenerative changes is not known Perhaps the most commonly held view is that they result from ordinary "wear and tear" i e from cumulative repeated trauma of various sorts

Although there is little doubt that repeated injury of one form or another frequently plays a role in this disorder this concept does not explain the disease completely A striking exception to this hypothesis is the common involvement of the distal inter

of the spine proper The synovitis is confined to the posterior intervertebral joints since they are the only true diarthrodial joints of the vertebral column Later the spinal ligaments become calcified Demineralization of vertebral bodies presumably on the basis of osteoporosis may appear during any phase of the disease

Spondylitis begins in most cases insidiously with stiffness of the back after inactivity Patients then develop lumbar pain with root radiation often sciatic and some limitation of forward bending Stiffness early in the course of the disease is frequently caused by spasm of the spinal muscles and may be completely alleviated by muscle relaxants such as curare The lumbar spine gradually loses its normal lordosis With progressive involvement of the costovertebral joints chest expansion diminishes and pain may be elicited by deep inspiration coughing or sneezing As the spine fuses it may be held erect the so called poker spine but more frequently the pull of the spinal muscles results in kyphosis scoliosis or both Frequently the head becomes fixed in forward displacement Peripheral joint involvement may either precede or follow spinal disease In many instances it is brief and intermittent but in one fourth of the patients it persists characteristically in the root joints (shoulders and hips)

Although the course of the disease may vary a good deal the usual pattern is persistent activity over the first 2 or 3 years The patients during this period continue to have pain run low grade fever lose weight develop anemia and maintain a high sedimentation rate As the spine fuses pain diminishes and finally disappears on the average 10 years after onset In contrast to patients with rheumatoid arthritis the majority roughly three fourths with spondylitis continue to lead relatively normal lives less than 10 per cent become totally incapacitated Many investigators feel that patients with spondylitis are better motivated than those with peripheral rheumatoid arthritis This however may only reflect the different kind of incapacity produced by the two diseases

The general principles of management are similar to those employed in rheumatoid arthritis—the relief of pain and the preservation of the best possible skeletal function For analgesia salicylates in the fullest tolerable doses should be tried first X ray therapy affords pain relief to many but not all patients It is administered to painful areas of the spine 600 r in air per portal in divided doses The response may be immediate or delayed for 1 or 2 months The courses of therapy may be repeated every 3 to 6 months The customary precautions against spray irradiation should be exercised In spite of the relief of pain by radiotherapy the disease as shown by x ray changes continues to progress Phenylbutazone (Butazolidin) appears to be more effective in spondylitis than in peripheral rheumatoid arthritis It is particularly helpful in minimizing periodic painful attacks in ambulatory patients The contraindications complications and appropriate prophylactic measures as described in the section on peripheral rheumatoid arthritis are equally applicable in spondylitis The indications for adrenocortical steroid therapy are fewer than in rheumatoid arthritis being largely confined to patients with severe sustained disease in whom the peripheral joints are also seriously affected

Special attention should be paid to keeping deformities to a minimum by seeing to it that fusion takes place in the optimal position The bed should be kept flat by placing a board underneath a firm mattress and the head pillow small to prevent kyphosis and neck flexion A small pillow under the lumbar spine may preserve the normal lordotic curvature Exercises of the paravertebral abdominal and respiratory muscles are designed to maintain a straight back and neck and to retain ventilatory sufficiency Muscle relaxants may be useful in the early phases of the disease Back braces may help to combat thoracic kyphosis Rarely in the extremely deformed patient an osteotomy of the lumbar spine may be indicated

Psoriatic Arthritis (or Arthropathy)

Psoriasis occurs in approximately 3 to 8 per cent of patients with rheumatoid arthritis It is generally agreed that the association between these two common diseases is not merely coincidental The psoriasis usually antedates the arthritis by months or years although they may emerge simultaneously or the arthritis may be the first to appear

In most patients the articular lesions are indistinguishable from those of rheumatoid arthritis on clinical roentgenographic and pathologic grounds In a few patients however there is striking involvement of the distal interphalangeal joints with marked articular destruction Frequently this form of arthritis is associated with psoriatic changes of the nails of the corresponding digits The involvement of the distal interphalangeals is the most prominent distinguishing feature and according to some rheumatologists is essential for the diagnosis of true psoriatic arthropathy These joints may be involved alone or in combination with others more characteristic of rheumatoid arthritis Radiologically the changes in the terminal joints may resemble those of gout sarcoid or degenerative joint disease In both groups of psoriatics i e those with classical rheumatoid arthritis and those with arthritis of distal joints subcutaneous nodules are conspicuously absent and serologic reactions are rarely positive

The principles and details of management are similar to those of rheumatoid arthritis The joints

nodules The sheep cell agglutination test is nega tive

Even though x ray changes of an affected joint may be those of DJD the articular symptoms and signs may be caused by a coexistent joint disorder such as rheumatoid arthritis or gout In such cases objective evidence of inflammation may have great diagnostic significance Errors of overdiagnosis are commonly made in cases demonstrating osteophy tosis of the spine this rarely gives rise to symptoms In patients with back symptoms some other process such as a herniated nucleus pulposus and not the DJD may be responsible At any rate if pain believed to be attributable to DJD is severe and fails to respond to the usual measures one must rule out other diseases such as metastasis of a malignancy to bone multiple myeloma or osteo myelitis

Management The most important feature in the care of the patient with degenerative joint disease *is to advise him that although his disease is annoy* ing and at times uncomfortable it is not serious and not the kind (like rheumatoid arthritis) that causes severe pain disability and crippling By such re assurance the patient is spared the anguish of the pronouncement that he has "arthritis and "nothing can be done Conservative measures—adequate rest of the involved joints physical therapy includ ing corrective exercises and safe analgesics such as salicylates—usually suffice Attention should be directed toward eliminating or minimizing second ary traumatic influences Obese patients should lose weight Certain occupational adjustments may be made Abdominal supports for lumbar spine disease aggravated by a sagging abdomen and a Thomas collar or head traction for cervical spine involve ment are other examples of ways to eliminate pre cipitating influences Repeated intraarticular injec tions of hydrocortisone are beneficial only in those patients with a superimposed nonspecific inflam matory response to fragmented cartilage or bone The *systemic use of such potentially hazardous* agents as adrenocortical steroids or phenylbutazone should be discouraged Corrective orthopedic surgi cal methods are useful for severely disabled and painful hips and knees unresponsive to conservative management

HYPERTROPHIC OSTEOARTHROPATHY

Definition This disorder also known as hyper trophic pulmonary osteoarthropathy *osteoarthropa thie hypertrophiante pneumique* secondary hyper trophic osteoarthropathy and Marie Bamberger syndrome is characterized by (1) clubbing of the fingers and toes (2) chronic periostitis with new bone formation at the distal ends of the long bones and (3) arthritis In the vast majority of cases this syndrome is secondary to one of several diverse serious chronic illnesses in other parts of the body in the remainder it is hereditary or idiopathic Be cause of its frequent association with diseases of the lung the disorder is often called "hypertrophic pulmonary osteoarthropathy" but this is a restric tive designation in that the primary disease may reside elsewhere as in the heart liver or gastro-intestinal tract

Formerly chronic suppurative conditions such as bronchiectasis were the most common underly ing diseases but now pulmonary neoplasms head the list Osteoarthropathy may appear several months before the first symptom or sign of broncho genic carcinoma

Classification Hypertrophic osteoarthropathy oc-curs either *symmetrically* all four extremities usually being involved or *unilaterally* affecting only one extremity more commonly an upper Symmetrical disease is subdivided into *acquired hereditary* and *idiopathic forms The acquired form is further* categorized according to the location of the under lying condition

1 *Pulmonary* Various pulmonary pleural and mediastinal disorders lead to this syndrome It occurs in 5 to 10 per cent of cases of bronchogenic carcinoma it has a high incidence in pleural tumors but is rare in tumors which have metastasized to lung Chronic infections include bronchiectasis lung abscess and empyema It is rare in tuberculosis Arthropathy has occurred with Hodgkin s disease aortic aneurysm and other disorders of the medi astinum

2 *Cardiac* Hypertrophic osteoarthropathy oc curs in cyanotic forms of congenital heart disease but is not seen in noncyanotic forms It is sometimes present in subacute bacterial endocarditis

3 *Hepatic* The incidence of this syndrome is high in cholangiolitic biliary cirrhosis but much lower in obstructive biliary portal and postnecrotic cirrhosis

4 *Gastrointestinal* Most of the intraabdominal conditions leading to osteoarthropathy are charac terized by chronic diarrhea They include ulcerative colitis and regional enteritis amebic and bacillary dysentery intestinal tuberculosis polyposis of the colon neoplasms and idiopathic steatorrhea

5 *Miscellaneous* Although it is very rare in spontaneous myxedema (and cretinism) several cases of osteoarthropathy have developed following thyroidectomy for Graves s disease Isolated cases have been described in chronic urinary tract in fections syringomyelia and various other disorders

The *hereditary* form of osteoarthropathy is rare and is distinguished from the acquired form by remarkable thickening of the skin over the face and limbs and by little bone or joint pain It is in herited as a *mendelian dominant* appears shortly

phalangeal joints (Heberden's nodes) These joints are not subject to any more frequent or severe mechanical injury than others such as the metacarpophalangeals which are rarely involved in DJD Necropsy studies have failed to uncover any difference in the incidence of this disorder between laborers and sedentary workers The primary cause does not seem to be vascular in view of the poor correlation between various vascular disorders or more specifically vascular lesions in synovial tissues and the articular changes of DJD

Heredity clearly plays a role in the pathogenesis of Heberden's nodes They are ten times more common in women than in men Stecher showed that they are inherited as a sex influenced characteristic dominant in the female and recessive in the male However the importance of heredity or constitution in the pathogenesis of DJD at other sites has not been demonstrated

Pathology The initial step in the chain of pathologic events in DJD is degeneration of articular hyaline cartilage Grossly the cartilage becomes less elastic yellow and more opaque Under the microscope the surface is made uneven by the appearance of shallow linear furrows which later deepen into clefts or fissures running perpendicular to the surface of the cartilage At this stage the articular surface appears much like velvet on gross examination The cartilage cells form clusters Later there is fraying and then ulceration In this manner the hyaline cartilage is gradually destroyed

In response to this primary injury certain secondary productive or hypertrophic changes ensue In areas where the articular cartilage becomes thin the underlying calcified cartilage becomes thick and dense In the neighboring subchondral bone there is proliferation of fibroblasts endosteal cells and blood vessels This subchondral granulation tissue then breaks through the calcified cartilage to reach the surface of the joint space This surfacing of new bone which later thickens and becomes highly polished is called *eburnation* As a result perhaps of the response to injured cartilage and blood vessel proliferation bony excrescences or osteophytes begin to form at the joint margin These consist of cancellous bone the marrow spaces of which are continuous with those of epiphyseal marrow

Synovial changes occur late and consist of a tissue response to the deposition of debris such as fragments of degenerating cartilage or bone The synovial membrane may appear slightly hypertrophic mostly from fibrosis and with little cellular reaction In advanced cases fibrous thickening and contraction of the joint capsule may be intense Although the mechanism of pain production in this disease is not well understood it is possible that this shrinkage of the joint capsule supplied as it is with somatic and autonomic fibers may be responsible

Clinical Features Only a small proportion of patients with degenerative joint disease have symptoms from the disease Symptoms develop insidiously and consist chiefly of joint pain and stiffness The pain is characteristically aching and mild it appears with exercise of the part and abates with rest The stiffness or articular "jelling" develops after prolonged rest in a fixed position and disappears a few minutes after resuming activity in contrast to that of rheumatoid arthritis which may last for hours Although the disorder is frequently progressive it rarely causes the degree of discomfort and invalidism encountered in rheumatoid arthritis

Objectively the joints may appear entirely normal even in the patient with symptoms Joint enlargement when present is the result of secondary hypertrophy of bone The enlarged joints feel hard and knobby unlike the soft fluctuant swelling in rheumatoid disease There may be tenderness but rarely excessive warmth or erythema In the later stages a grating sensation or crepitus may be felt on moving the affected joint There are no diagnostic laboratory abnormalities or changes in the synovial fluid

In the symptomatic patient the roentgenographic appearance may be normal or exhibit one or more abnormalities These include (roughly in order of advancing disease) unevenness and narrowing of the joint space secondary to destruction of cartilage sharpening of the articular margins irregularity and widening of the articulating surfaces bony sclerosis or eburnation as shown by heightened radiopacity at the ends of bone osteophytes or marginal lipping and bone cysts Osteoporosis does not result from DJD when present other causes should be sought

The most commonly involved joints are those that bear weight (knees hips and lumbar spine) and also the cervical spine shoulders and distal interphalangeal joints of the fingers

Diagnosis Since DJD and rheumatoid arthritis the two most common forms of chronic joint disease in the middle aged and the elderly differ so widely in both prognosis and management it is important to distinguish one disorder from the other In virtually every instance this is readily accomplished Differentiation should never be made on the basis of age alone In contrast to rheumatoid arthritis DJD is confined to the joint structures and is not a widely disseminated systemic disease There are no constitutional symptoms and signs such as fever weakness fatigability anorexia weight loss or muscular wasting nor are there laboratory abnormalities such as anemia leukocytosis elevated sedimentation rate or hyperglobulinemia The joints are not hot or red and there are no subcutaneou

ration In cases where the osteoarthropathy is severe and a satisfactory attack on the primary disorder is not possible relief of disabling symptoms has been obtained by intrathoracic vagotomy or adrenocortical steroid therapy

MISCELLANEOUS ARTHRITIDES

Palindromic Rheumatism

This controversial syndrome of unknown cause consists of recurring afebrile attacks of acute arthritis with pain swelling erythema heat and tenderness The arthritis appears suddenly usually involves a single joint and lasts a few hours or days Attacks are numerous and irregularly spaced during the intervals between them the joints appear normal and function properly Essential to the diagnosis is the absence of residual arthritis even after hundreds of attacks and normal values for the hematocrit and blood uric acid concentration The sedimentation rate may be elevated Some cases demonstrate paraarticular involvement but there are no constitutional symptoms or signs In spite of the fact that many patients diagnosed as having palindromic rheumatism eventually develop typical rheumatoid arthritis or gout the number of patients who seem to fit this description is high enough to warrant continued separate categorization and further study Treatment is symptomatic

Intermittent Hydrarthrosis

This uncommon idiopathic condition consists of joint effusions recurring regularly every 7 to 11 days over several years It is seen mostly in adolescents and young adults Typically it affects the knee (ankle or hip less commonly) and is unilateral The joints in addition to being swollen are often painful and restricted in mobility but not hot or red It is not a systemic disease there is no fever weight loss or muscular wasting there is no anemia and the sedimentation rate is normal Strictly defined it is not a simple hydrarthrosis because biopsy usually reveals a villous synovitis indistinguishable from that of rheumatoid arthritis There is a leukocytosis in the synovial fluid polymorphonuclears predominating Most patients with this diagnosis subsequently prove to have rheumatoid arthritis However 150 cases have been reported with these characteristic periodic effusions over periods as long as 22 years with no residual deformity The disease is refractory to salicylates and physical therapy Some workers believe this condition to be an unusual form of allergy because in a few patients elimination of a food item has coincided with cessation of attacks Antihistaminics are ineffective The response to the intraarticular injection of hydrocortisone is usually favorable Careful exclusion of other rheumatic disorders is essential

Psychogenic Rheumatism

This term refers to the rheumatic manifestations of psychoneurosis in which patients undergoing psychic trauma complain of stiffness pains in joints tendons or muscles and limitation of joint motion In the American Armed Forces during the Second World War psychogenic rheumatism was thought to be the most common rheumatic disease in the British forces such cases were labeled "fibrositis" Essential for this diagnosis are good general health emotional instability lack of joint changes clinically and radiologically normal laboratory findings vacillating complaints and failure to respond to analgesics and physical therapy Some investigators feel that a category of psychogenic rheumatism is unjustified there probably being some organic basis for the symptomatology

NONARTICULAR RHEUMATISM

The patient complaining of "rheumatism" often is referring to symptoms resulting not from joint disease per se but arising from dysfunction of other tissues near joints These include tendons bursae bones muscles nerves and adipose tissue This heterogeneous group of extraarticular disorders is probably responsible for more rheumatic complaints than any one of the various intrinsic joint disorders Approximately 30 per cent of patients who attend arthritis clinics in the United States have nonarticular rheumatism

Fibrositis

This is a controversial unfortunate term which Gowers introduced in 1904 to describe the chronic inflammation of fibrous tissue which he believed to be responsible for lumbago This concept was avidly adopted to explain the various aches and stiffness appearing in various sites of the body and fibrositis has become a wastebasket for many forms of nonarticular rheumatism In addition to stiffness and soreness there are often tenderness and limitation of motion of the affected part The presence of nodules has been overemphasized in many instances these are really fat hernias The frequent sites of pain are the lower back gluteal region neck shoulder and chest Fatigability is the only constitutional manifestation Precipitating factors include various infections such as malaria influenza or pleurodynia trauma environmental experiences such as overexposure to cold dampness or drafts more specific connective tissue disorders such as bursitis or tenosynovitis fat hernias and emotional stresses in a neurotic individual In many

after puberty progresses for about 10 years and remains stationary thereafter

Many cases designated as *idiopathic* are examples of the hereditary form or acquired disease in which the primary condition is unrecognized A few cases of typical osteoarthropathy are however unexplainable

Unilateral clubbing and osteoarthropathy are most commonly caused by aneurysm of the aorta innominate or subclavian Other causes are apical lung cancer axillary tumors subluxation of the shoulder and brachial arteriovenous anastomoses

Pathology The basic lesion is chronic inflammation of periosteum synovial membrane joint capsule and adjacent subcutaneous tissue The periosteum early in the disease exhibits edema and round cell infiltration and at its inner margin osteoid matrix Initially only scattered foci of new bone appear later the distal segments may become completely encased by new bone

The synovial membrane articular capsule and the subcutaneous tissue about the affected bones and joints become thickened and chronically inflamed There may be an intermittent hydrarthrosis Rarely the synovitis goes on to pannus formation ankylosis and degeneration of cartilage

Pathogenesis Theories which have been advanced for the mechanism of osteoarthropathy include (1) chronic infection (2) action of toxins absorbed from the primary focus (3) capillary stasis caused by elevated venous pressure (4) arterial hypoxemia (5) local hypoxia (6) action of local toxins formed as a result of circulatory disturbances (7) anterior pituitary overactivity (8) thyroid underactivity and (9) the elaboration by pleural mesothelial cells of an osteoblast stimulating substance None of these hypotheses accounts for more than a small proportion of cases

The first and only experimental reproduction of this condition was achieved by Mendlowitz and Leslie in the dog by anastomosing the left pulmonary artery to the left auricle thus creating a situation similar to cyanotic congenital heart disease As the osteoarthropathy developed the systemic cardiac output increased (the pulmonary blood flow remaining normal)

After resection of a lung abscess or tumor symptoms and signs of osteoarthropathy frequently subside within a few days The speed of this improvement suggests that the alterations in the peripheral circulation are corrected rapidly perhaps by interrupting an abnormal pulmonary vascular reflex This hypothesis is supported by a recent report of prompt improvement in hypertrophic osteoarthropathy after dividing the vagus in five patients with inoperable lung cancer Thoracotomy alone is ineffective

Manifestations In clubbing the fingertips feel warm and slightly burning but pain is unusual The first change is thickening about the nail bed which can be detected by a reduction in the angle made by the nail and the dorsal plane of the distal phalanx normally about 15 degrees Profuse sweating of the hands and feet is common

Rheumatic complaints vary greatly in severity There may be deep seated burning pain and exquisite tenderness over the distal ends of the bones in acute and advanced cases About the affected bones and joints the skin may be dusky red warm and tender and the subcutaneous tissue thickened The joints may be swollen and their mobility restricted Most commonly involved are the knees ankles wrists elbows and metacarpophalangeal joints There may be slight fever

In the early stages of clubbing the terminal phalanges appear normal on x ray but with advancing disease reveal flaring of the ungual process and osteoporosis The x ray evidence of osteoarthropathy consists of periosteal thickening along the shafts of the long bones appearing first and being thickest in the region of the distal epiphyses especially at the points of musculotendinous insertion The periosteal elevation spreads proximally as the disease progresses Later the cancellous portion of the involved bone becomes osteoporotic and the cortex becomes thin

The course of hypertrophic osteoarthropathy reflects the activity of the underlying disease In cases where it waxes and wanes with exacerbations and remissions of the primary condition the roentgenograms show a tree trunk like layering of thin sheets of newly formed bone In cases secondary to chronic suppuration the osteoarthropathy emerges insidiously and is usually mild In cases secondary to lung tumors the clubbing and arthropathy may appear very suddenly Articular symptoms and signs sometimes antedate clubbing of the fingers but this is unusual

Diagnosis When clubbing arthritic symptoms and periosteal proliferation by x ray are all present this syndrome is easily recognized The patient in whom arthritic symptoms predominate is often thought to have rheumatoid or some other form of polyarthritis In patients with erythema and superficial tenderness especially about the ankles thrombophlebitis is a frequent diagnosis Differentiation from acromegaly is usually not difficult The diagnosis cannot rest on evidence of periosteal proliferation alone because scurvy syphilis trauma lymphangitis varicose veins and other conditions give rise to periosteal disorders

Treatment Therapeutic efforts in hypertrophic osteoarthropathy should be directed toward the elimination of the underlying condition or its amelio

266 DISEASES AFFECTING THE SKIN

Donald M Pillsbury

The physician possessed of reasonable familiarity with the principles of applied anatomy physiology and chemistry of the skin and with the dozen or so chief patterns of disease which it presents will be able to classify over 90 per cent of all dermatologic syndromes with reasonable accuracy and to treat most of them effectively If in the course of the initial examination the skin lesions of a patient can be classified as representative of a common or uncommon disease as banal or serious as a local disturbance or a manifestation of systemic disease much has been accomplished Many diseases of the skin can be diagnosed with accuracy on inspection providing the examination is adequate and complete as surely as the pathologist recognizes a characteristic cytologic picture Others require further study utilizing all the resources of general medicine and of special laboratory procedures

Dermatologic diseases are encountered rather frequently by the general physician and by all medical specialists On the basis of the enormous United States Armed Forces experience during the Second World War it is clear that any general physician who is practicing in a Temperate Zone will find that some 7 to 15 per cent of his patients present themselves with a chief complaint of a disease affecting the skin In warm humid tropical climates this incidence rises to 25 per cent or more Under conditions of disaster and war the skins of the affected population offer a particularly fertile field for microorganisms and parasites In industry various dermatoses comprise by far the largest group of occupational medical diseases The scope of internal medicine and its subspecialties is so broad and complex as to make it impossible for any physician to be familiar with all of them in any detail In dermatology is in other medical specialties however the most rewarding initial approach is through an understanding of the general principles of anatomy physiology and pathology which have useful clinical application to both diagnosis and treatment

It is essential for the internist to gain an understanding of the characteristics of the principal syndromes which affect the skin In a number of these experience has shown that involvement is almost entirely mucocutaneous and there is no need for extensive procedures of examination other than an adequate general physical evaluation and a few key laboratory studies as in pityriasis rosea certain types of dermatitis acne dermatotropic viral infections (warts molluscum contagiosum) vitiligo most diseases of the hair and nails moderate genetic changes such as mild ichthyosis and benign tumors which may be recognized on clinical examination In most patients these diseases are not particularly disabling and the eventual outcome is ordinarily good Disability and subsequent systemic disease most commonly *result from mistreatment* e g the application of known sensitizing topical agents such as sulfonamides certain antibiotics and antihistaminics the excessive use of ionizing radiation therapy and more and more prominently from the prolonged administration of corticosteroids in doses which are almost certain to produce undesirable physiologic effects

In a second group of diseases affecting only the skin during the initial phase lack of recognition of the nature of the process may be followed by the progression of systemic disease Examples of this group of dermatoses include mild drug reactions the initial manifestations of atopy mild contact dermatitis with continued exposure to the offending allergen bacterial infections which are initially superficial (impetigo and acute folliculitis) but which may produce irreversible systemic infection if not promptly dealt with parasitic infestations such as scabies and pediculosis certain tumors such as active junction type nevi or basal cell and prickle

instances however no cause or precipitating factor is found

Tendinitis and Tenosynovitis

Inflammation of tendons and tendon sheaths may be associated with various types of arthritis or occur independently It is more frequent in gonococcal arthritis (48 per cent of cases in one series) than in any other form of arthritis Occasionally one finds gonococcal tenosynovitis without arthritis Tuberculous tenosynovitis is chronic and destructive The most common site is the wrist Tenosynovitis also occurs in rheumatoid arthritis gout and palindromic rheumatism

Nonspecific tenosynovitis is thought to be a consequence of single or repeated injuries incurred during movements demanding strength and speed The wrist and ankle tendons and sheaths are most commonly involved If conservative therapy (immobilization heat and analgesics) fails local injection of hydrocortisone or surgical excision of the sheath may be helpful

Bursitis

This term is used loosely by patients to signify pain in one or both shoulders To the physician it denotes pain in the region of one of the 140 or more bursae in the body The most commonly affected deep bursae (those situated between bony prominences and muscle or tendon) include the subacromial subgluteal supratrochanteric and Achilles bursae The most frequently involved superficial bursae (those situated between bony prominences and skin) are the olecranon and prepatellar Subacromial bursitis is estimated to be the cause of shoulder pain in 80 per cent of patients who do not have evidence of rheumatic disease elsewhere Its numerous synonyms include subdeltoid bursitis calcific bursitis calcific tendinitis periarthritis of the shoulder and Duplay s disease

The pathogenesis of subacromial bursitis is obscure The generally held concept is that acute or chronic trauma leads to partial rupture of the tendon of one of the short rotator shoulder muscles (supraspinatus infraspinatus teres minor and subscapularis) Calcium is then deposited at the traumatized site Inflammation within and about the bursa is thought to be secondary to the tendinous necrosis and calcification

In acute subacromial bursitis agonizing pain appears suddenly in the region of the shoulder joint and is aggravated by motion especially by abduction of the arm The pain often radiates into the neck or down the lateral aspect of the arm even to the fingertips There is exquisite tenderness over the greater tuberosity of the humerus In approximately half the cases roentgenograms of the shoulder reveal one or more calcific deposits over the greater tuberosity and localized atrophy of adjacent bone The acute attack subsides completely or passes into a chronic phase which is usually mild

Adhesive capsulitis (also called adhesive tendinitis chronic adhesive bursitis or frozen shoulder) is distinguished from subacromial bursitis by a more insidious onset less pain and more stiffness Dense adhesions form between the opposing surfaces of the subacromial bursa Some believe that the initial change is degeneration of the biceps tendon It is thought to result from prolonged immobilization senescent change or trauma In advanced cases the arm becomes locked at the side and the shoulder muscles become atrophic

Therapeutically the acute attack of bursitis may require no more than rest immobilization with slings or splints and analgesic drugs The local injection of procaine or hydrocortisone affords prompt relief in some but not all cases The value of radiotherapy has not been established Aspiration or surgical removal of the calcific deposit is recommended for persistent disabling disease In adhesive capsulitis one may have to resort to manipulation of the shoulder under anesthesia

Table 135 SKIN UNITS

Cells and layer		*Epidermal appendages*	*Systems*
Keratinocyte, Melanocyte	Epidermis	Hair, Sebaceous gland	Vascular, Neural
Fibrocyte, Histiocyte, Mastocyte	Dermis	Apocrine gland	Extraneous cells
Lipocyte	Subcutaneous	Eccrine sweat gland	Myeloid, Lymphoid

The clinician perceives three fundamental morphologic changes in the skin in *color mass* or *fluid content* The color changes (macules plaques) usually involve the melanocyte or the vascular system Changes in mass (papules nodules tumors) may result from hyperplasia of any of the units listed Growths derived from the keratinocyte *melanocyte and blood vessels are by far the most* common The change in free fluid of the epidermis (vesicle bulla) is fundamentally a reaction of the keratinocyte to injury In the dermis extravascular fluid masks itself clinically as a solid mass (urticaria)

KERATINOCYTE *Keratinization is the most important function of the epidermis* Disturbances or lack of other functions are inconvenient but rarely of crucial importance Complete failure of keratinization is incompatible with life In addition to the hyperkeratinization which results from chronic injury certain genetically influenced changes may be seen an example being congenital hyperkeratosis of the palms and soles Psoriasis is another disease in which there is a disturbance of keratinization with failure of the cycle to be completed In ichthyosis the principal change appears to be a retarded exfoliation of the stratum corneum This may reach severe degrees and be accompanied by atrophy or absence of eccrine and sebaceous glands

An important clinical consideration is that the elasticity of the stratum corneum and the resistance of the skin to chapping are dependent principally upon the water content of the keratin not the oil content Reduction of the water content by low environmental humidity chemical agents or senescence reduces the protective capacity of the horny layer There is no evidence that ordinary ichthyosis is associated with thyroid hypofunction or dysfunction and the administration of thyroid extracts for dryness and ichthyosis of the skin is illogical

MELANOCYTE This is the second important cell of the epidermis In the albino a genetic flaw in enzyme systems (tyrosinase) results in complete failure of pigment formation Negro skin contains an increased amount of melanin but the same number of melanocytes as white skin Local areas in which the melanocyte elaborates too little melanin (vitiligo leukoderma) or too much melanin (chloasma freckles) are frequent

The melanin synthesizing capacity of the skin is regulated by the melanocyte stimulating hormone (MSH) of the anterior pituitary gland There is a balance between this hormone and those elaborated by the adrenal cortex which furnishes an explanation for the pigmentation seen in Addison s disease and perhaps in pregnancy

The melanocyte reacts to injurious stimuli by producing less or more melanin Certain superficial inflammatory processes e g seborrheic dermatitis may produce temporary depigmentation but the ordinary response is increased pigment This is useful in protecting the skin from acute or chronic changes The incidence of epithelioma is directly related to the amount of sunlight to which the skin of the patient is exposed and to a lessened ability to lay down protective melanin in the epidermis With aging the activity of melanocytes varies and dyspigmentation results

Neoplastic change in the melanocyte accounts for the most common of all skin lesions the ordinary pigmented nevus or mole and is the origin of the most malignant of all skin tumors (malignant melanoma) Simple hyperplasia leads to hyperpigmented flat macules (lentigo junction nevus) or even palpable masses Usually brown or black nevi may be flesh colored indicating an absence of function in the hyperplastic cells Not all melanocytic nevi are epidermal Overgrowth of pigmented cells in the dermis gives a blue color (blue nevus mongolian spot)

The interpretation of various types of pigmented lesions in the skin in terms of the possibility of malignant melanoma is a common and vexing clinical problem which is discussed in some detail later

PATHOLOGIC PATTERNS IN THE CORIUM The three principal cells of the corium or dermis are the *histiocyte* the *fibrocyte* and the *mastocyte*

The master cell of the dermis is the fibrocyte the source of collagen and ground substance Normal functioning of this cell is essential to skin repair Unrestrained reparative activity can lead to large deposits of collagen (keloid) This condition is a steady increase in scar tissue which may continue indefinitely in some individuals principally Negroes Benign overgrowth of the fibrocyte produces a simple fibroma Malignant change is rare and produces fibrosarcoma or "spindle cell sarcoma Cortisone prevents the normal development of collagenous tissue and vitamin C deficiency interferes with the elaboration of normal reticulum

The *histiocytes* normally phagocytize particulate matter including melanin (melanophore) lipids (foam cell) hemosiderin some tattoo pigments viruses bacteria fungi and protozoa When confronted with larger masses of material (uric acid crystals petrolatum) histiocytes commonly fuse to

cell epitheliomas in which cure is almost always possible by early treatment and a wide variety of industrial dermatoses hyperpigmentary disorders and photosensitivity reactions

A third group of diseases affecting the skin with which some familiarity is essential includes many conditions which are relatively uncommon but in which an early diagnosis may sometimes lead to complete cure or at least a slower progression of the disease In this group may be included pemphigus syphilis discoid lupus and systemic L E scleroderma miliaria (in which extension of the poral closure may lead to marked disturbances in heat regulation) tuberculosis deep fungous infections sarcoid various purpuras some xanthomas diphtheria cutis many parasitic infestations cutaneous manifestations of lymphomas angiomas acanthosis nigricans psychocutaneous syndromes (especially factitial dermatitis) and chronic effects of physical agents particularly sunlight and cold

In a fourth large group of diseases in which the skin is affected the mucocutaneous manifestations are variable and often incidental though frequently they represent the chief sign through which the nature of the disease may be suspected Examples include the viral exanthems rickettsioses sarcoidosis erythema nodosum leprosy dermatomyositis peripheral vascular diseases erythema multiforme several metabolic diseases neurocutaneous syndromes (adenoma sebaceum) spider angiomas in hepatic disease pruritus as the initial sign of lymphomas or hepatic disease etc

In addition to these there are a considerable number of localized banal conditions in which patients have a consuming interest though they are of no general medical importance A reasonable interpretation of these may often be given not necessarily in terms of any specific syndrome on the basis of the etiologic and physiologic forces involved e g in disturbances of growth or pigmentation of hair and nails Of all the sources of interest and concern of patients about their skin that of possible cancer is paramount and this is constantly increasing as cancer education campaigns and publicity increase An assessment of dermal neoplasms examples of which will be found in every patient examined is a requisite of every general medical evaluation Fortunately the vast majority of tumors and excrescences of the skin are benign and can be recognized as such on close inspection Others must be suspected of being malignant or are patently so In the latter circumstance the sooner the tumor is classified accurately the better

In a short chapter of this type it is not feasible to include detailed descriptions of the wide variety of changes to which the skin is subject This discussion will therefore be confined to a brief summary of the means by which a diagnosis may be established and of certain special laboratory procedures which are not ordinarily used in general medicine A knowledge of diseases of the skin in terms of basic principles obviates much of the need for the use of long and complex designations of individual diseases and their variants

Applied Anatomy and Pathology of the Skin

The skin is a complicated membrane containing a variety of glands nerves vessels lymphatics and muscles It is stratified anatomically in distinct layers epidermis corium (true skin) and subcutaneous tissues

The *epidermis* is about as thick as this paper and highly cellular The *corium* is composed mainly of noncellular collagenous tissue and its energy needs are low It is twenty to thirty times thicker than the epidermis and rests upon the thick *fatty subcutaneous tissue* The *skin appendages* are of two kinds The hair and nails comprise the *keratinized* appendages the apocrine sebaceous and eccrine glands the *glandular* appendages The skin is not uniform In some regions it is adapted to particular purposes and varies in thickness suppleness and looseness The skin of the eyelids for instance is considerably thinner and looser than that of the palms and soles The appendages are characteristically concentrated in certain regions The palms for instance contain eccrine sweat glands but no sebaceous glands the ear lobes contain sebaceous glands but no eccrine glands The reactions of hairy skin differ considerably from those of glabrous skin Intertriginous areas must withstand special stresses The specialized features of the skin in different regions clearly influence the distribution of lesions in certain diseases

The skin serves as an essential anatomic and physiologic shield between the body and its environment Its principal functions are (1) mechanical protection against physical microbiologic and chemical injury (2) perception of a wide variety of noxious stimuli (3) adjustment to environmental temperature (4) prevention of absorption of external substances and loss of body fluids (5) provision of an elastic adaptable covering which permits vigorous movements of underlying structures

Pathologic Patterns in the Skin The fundamental pathologic changes in the skin are few and simple Actually any cellular unit of the skin has but a triad of basic responses to multiple and diverse factors which cause disease These are (1) *functional*—impairment of function in the absence of morphologic changes (2) *inflammatory*—degenerative changes following cellular injury and (3) *proliferative*—increase in the number of cells of given type viz tumors benign or malignant

For purposes of analysis Table 135 presents the units of the skin which may undergo changes

function Its secretion is sterile and odorless but on contamination with the ordinary micrococci of the skin surface it becomes rancid and is the chief source of body odor

The apocrine gland reaches its full development at puberty and disappears with age The chief disease arising from it is *hidradenitis suppurativa* This is not common but may be extraordinarily disabling The sequence of events appears to be in many ways similar to that seen in acne namely a poral closure and blockage with resultant rupture of ducts and extrusion of apocrine secretion into the skin In some individuals infection occurs which may be very difficult to distinguish initially from furuncles If the process is allowed to go unchecked extensive coalescent undermining abscesses form and may be exceedingly persistent The common sites of involvement are the axillas and the anogenital region In some instances cure cannot be obtained until complete excision and grafting of the areas containing the infected apocrine glands are carried out

The *eccrine sweat gland* is an organ of importance in the maintenance of body temperature and is a contributor to a variety of diseases of the skin Man achieves homeostasis in large measure through the action of the sweat glands which flood the skin surface with water to cool it and of the cutaneous blood vessels which dilate or constrict to produce dissipation or conservation of body heat

The master control of the eccrine sweat gland is in the hypothalamus It integrates the effect of thermal sensory impulses which arise in the skin with the blood temperature Either an increase in the skin temperature itself or an increase in blood temperature will result in hypothalamic discharges which relayed through the sympathetic nervous system cause immediate bursts of activity in sweat glands over the entire body There are no inhibitory nerves to the sweat glands Resection of the sympathetic fibers controlling the gland results simply in *anhidrosis*

Sweating may be induced by other than thermal stimuli It may occur on the face as a result of a gustatory stimuli or in association with visceral lesions Sweating may occur as a result of conditioned reflexes i e in anticipation of a warm environment or other stimulus to sweating Emotional sweating is a common experience and has considerable clinical significance in perpetuation of certain types of inflammatory lesions The eccrine sweat gland responds very promptly to both cholinergic and adrenergic drugs Eccrine sweating may be inhibited by atropinelike agents which block the cholinergic stimulus However the clinical usefulness of such therapy is small because no such compound has specific selective effects upon the sweat gland and doses necessary to inhibit sweating produce annoying physiologic effects in other organs

The sweat gland is of no importance as an excretory organ for body wastes though sweat contains small amounts of lactate urea and ammonia and has a level of chloride which may vary from one to two times that of the plasma chloride The chloride level of sweat reflects the circulating level of corticosteroids During the process of acclimatization to heat the level of chloride in sweat drops appreciably Without specific testing of a patient to a standardized heat stimulus it is difficult to be certain of the functional status of his sweat glands

The universal distribution of sweat glands makes it likely that some of them undergo secondary changes of lesser or greater significance in every inflammatory skin lesion Sweat gland involvement may not be perceptible clinically since the gland has no visible surface representation as does the hair follicle and furthermore its secretory function is impossible to assess in the presence of scales exudate and other skin changes Even primary affections of the gland such as miliaria (prickly heat) were for a long time labeled eczema because of the failure to note that the primary change which occurred was in the sweat glands

Anhidrosis may be localized to a single gland or be generalized It may result from a variety of causes including heat stroke surgical trauma to the hypothalamus responses to atropinelike drugs congenital absence of glands and sweat retention syndromes induced by cutaneous diseases It may be a source of unexplained fever tropical asthenia or heat stroke In patients with an anhidrosis of significant degree it may be noted that sweating of the face and neck will be marked but the rest of the skin shows no evidence of sweating

The disturbance of sweating which most clearly results from diseases of the skin is that which results from blockage of the ducts This occurs most frequently as a result of some cutaneous injury For instance blockage of a greater or less number of sweat ducts may be achieved regularly by such stimuli as a mild sunburn a contact dermatitis the application of adhesive tape for 48 hr or the prolonged application of a wet compress If the individual is not stimulated to sweat, either by warm environment or through emotional stimuli no secondary changes in the skin result However if there is a stimulus to sweating sweat may be extruded into the skin rather than on its surface through rupture of the ducts and this promptly results in itching and in a variety of characteristic inflammatory changes which are clinical variants of miliaria If the sweat duct blockage is superficial this is of no importance but if it is deeper the

form multinucleated foreign body giant cells In xanthomas multinucleated histiocytes filled with lipid droplets appear (Touton giant cells) In granulomas the histiocytes change into epithelioid cells which divide into another form of giant cell (Langhans) These are phagocytic and are distinctive of the general group of granulomas of the skin (syphilis tuberculosis leprosy sarcoidosis and deep mycoses)

The third principal type of cell in the corium is the *mast cell* This requires special histologic methods for its demonstration and is rarely seen in routine biopsy specimens The mast cell granules contain both heparin and histamine The mast cells are localized about the vascular system The signal protective role of the mast cell is shown by the fact that it releases its granules in response to any injury with production of immediate vascular changes and an outpouring of leukocytes and plasma from the blood stream This appears to be *the mechanism involved in the production of the triple response* and in dermographism

Overgrowth and aggregations of mast cells produce the condition known as *urticaria pigmentosa* which has been presumed to be a rare disease occurring almost entirely in childhood However this concept is being rapidly extended and the following table indicates the various findings which may be encountered in this condition

Table 136 CLINICAL AND LABORATORY FINDINGS IN THE MORE SERIOUS TYPES OF URTICARIA PIGMENTOSA (MASTOCYTOSIS)

Clinical

HISTORY Months to years with pruritus and dermographism
AGE Over 30 years
SEX Either
SUBJECTIVE SYMPTOMS Nausea vomiting weakness and weight loss
SKIN MORPHOLOGY Macular to nodular red to brown telangectatic
VISCERAL Hepatosplenomegaly

Laboratory

BIOPSY OF SKIN Proliferation of mast cells
BONE CHANGES BY X RAY Generalized osteoporotic osteosclerotic and thickened trabeculae of ribs vertebrae long bones and pelvis when first seen it suggests miliary metastases from carcinoma multiple myeloma or myelofibrosis of depressed bone marrow
STERNAL MARROW Mast cells sometimes present
BONE BIOPSY Nests or sheets of mast cells
SPLEEN OR LIVER BIOPSY Mast cells sometimes present
BLOOD STUDIES Low normal or leukopenic thrombocytopenic and sometimes a monocytosis

SOURCE Nickel W R Urticaria Pigmentosa (Mastocytosis) A M A Arch Dermatol 76 476–498 1957

LIPOCYTE In this the chief cell of subcutaneous fat tissue inflammatory changes are common Nonspecific fat necrosis manifests itself in subcutaneous nodules which may or may not be tender There is often a preceding history of trauma including the injection of various medicinal compounds or reactions to insect bites or thermal injury Occlusive peripheral vascular changes may impair circulation to the subcutaneous tissue sufficiently to result in formation of localized areas of fat necrosis

A *striking specific syndrome which involves* fatty tissue is Weber Christian disease (relapsing febrile nodular nonsuppurative panniculitis see p 1701)

Sebaceous Glands The distribution of these *glands* is distinctive The scalp and face have the greatest number the forehead may contain as many as one thousand glands per square centimeter and it is noteworthy that the glands are largest where they are most numerous Since the gland empties into the terminal hair follicle any condition causin *closure of the follicular ring may lead to retention* of formed sebum This may be followed by cyst formation or if there is rupture of the duct with escape of sebum and of bacteria into the skin moderate to marked chronic inflammatory changes may ensue *Chronic inflammation frequently* produces marked scarring in the skin and is very traumatic psychically in some patients Acneform eruptions may be seen in syndromes such as Cushing s disease and adrenocortical tumors Drug reactions to iodides are commonly acneform though they do not produce the precise sequence of events seen in this disease

Since the follicular unit is peculiarly susceptible to bacterial infection and since such infections may easily become chronic early treatment is desirable particularly in areas where the hair follicles are deep such as the bearded region and scalp It is to be emphasized however that in many instances chronic folliculitis is not due principally to bacteria but is essentially a foreign body reaction

The Sweat Glands Physiologic or anatomic disturbance of the eccrine or apocrine glands produces several distinct skin syndromes and may be a significant contributing factor to the chronicity of eczema and of fungous and bacterial infections

Though the *apocrine gland* is ordinarily referred to as a sweat gland its secretion is entirely different from eccrine sweat Lower Mammalia such as the ape and the dog show many apocrine sweat glands spread over the entire skin surface but in man the gland has become atavistic and regressive The glands are distributed primarily in the ear canal *the axillas the nipples* and the anogenital region though they may occur elsewhere The wax glands of the external auditory canal are modified apocrine glands In man the apocrine gland has little useful

age in relation to diseases of the skin is the increased vulnerability of aged persons to dermatitis ulceration or bacterial infection of the extremities secondary to peripheral vascular disease Destructive effects from all types of physical and chemical trauma are more severe and recovery is slower in older patients

Race Though many diseases affecting the skin occur more frequently in members of particular races this consideration is rarely crucial in diagnosis Pemphigus is more common in Jews but it can occur in Gentiles Kaposi's sarcoma is seen more frequently in patients from southeastern Europe but again this must not be a determining factor Psoriasis is infrequent in pure blooded Negroes but such persons are now rare outside of Africa Pediculosis particularly of the scalp is uncommon in Negroes Negroes also develop bizarre and exuberant cutaneous reactions in secondary syphilis and in sarcoid

Geographic Origin Some diseases affecting the skin can be acquired only under climatic and other conditions which render them contagious and endemic in certain areas For instance a person can almost never acquire leprosy if he has not lived for an extended period in an environment other than a Temperate Zone of Europe or of North America Certain treponemal diseases such as yaws pinta and bejel are seen only in tropical environments indeed bejel is encountered only in the eastern Mediterranean area Contact dermatitis to poison ivy does not occur in England because the plant does not grow there However individuals who are sensitive to poison ivy may have marked reactions to plants of the family Anacardiaceae which have an extensive geographic distribution e g the cashew nutshell mango tree Japanese lacquer tree and dhobie mark tree

While the strong geographic tendencies of some diseases are useful in making a list of diagnostic considerations more complete they may also lead to error If a patient states that he has spent some time in the tropics too great emphasis may be placed on the esoteric with neglect of aggravated forms of common diseases An individual who spends some time in a tropical climate but who is not a native is much more likely to have some very marked form of a disease commonly found in temperate climates such as miliaria or bacterial or fungous infections of the skin than he is to have a disease which is peculiarly and uniquely tropical Moreover it must be kept in mind that the geographic foci of many diseases are expanding and contracting for reasons that are not immediately apparent Coccidioidomycosis is common in the San Joaquin valley of California but there are other areas in the United States in which it is found Creeping eruption due to cat or dog hookworm is very common along the coastal areas of the Southeastern United States but during suitably warm weather with beaches densely populated may extend well into northern New Jersey "Jungle rot" (a thoroughly nondescript term) and "monkey pox" (widespread impetigo arising on miliaria) may be seen among the "natives" of cities such as Philadelphia and Baltimore during prolonged periods of steaming humidity

Seasonal Incidence Certain diseases have seasonal peaks Contact dermatitis will obviously be seen far more frequently during seasons when plants are growing A diffuse dermatitis from airborne or ragweed pollen is invariably first seen in any particular patient during the ragweed season but with recurrence of the disease recovery may be more and more delayed and the seasonal incidence less apparent Photosensitization reactions are at their peak during the summer season often occurring only in areas where there is no filtration of the sun's rays by smoke and other matter but with recurrences the direct relation of the reaction to sunlight may become less evident In all patients with chronic recurrent skin disorders the history of *climatic and other factors at the time of onset* is of great importance Prolonged questioning may be required to elicit this relation in proper perspective and detail

Many diseases including various types of dermatitis and superficial fungous infections become much worse during seasons of high environmental temperature Miliaria is caused almost entirely by this factor and is rare during cold weather Certain common diseases such as acne show variable responses in relation to season Acne is ordinarily improved by exposure to sun but it may become much worse in an environment of great heat and humidity A patient with congenital ichthyosis or senile atrophic skin is often worse during the winter because of the low humidity of artificially heated houses and prolonged exposure of the skin to the pleasure of hot baths Psoriasis and atopic dermatitis are ordinarily much improved during the summer months though not invariably so The very common disease pityriasis rosea shows increased incidence in the spring and fall for reasons which are a complete mystery Erythema multiforme of the recurrent urticarial or bullous types may occur principally during the spring through factors which are likewise unknown

Personal Hygienic and Occupational Factors The skin is subjected to a wider variety of traumatic stimuli than any other organ of the body Through a number of finely adjusted physiologic mechanisms it performs a vital service in the life of the person which it contains It does this with a surprising capacity to maintain its own integrity and functions There are few diseases of the skin in which environ

itching and inflammatory changes and trailing complications resulting from scratching and infection may be very disabling

Special Features of the History in Dermatologic Diagnosis

The *medical history* in a patient with a disease affecting the skin should be obtained with the same care that is exercised in a patient with any general medical or surgical illness However skin lesions are often too quickly assessed as trivial and unimportant their precise extent is undetermined and their general medical importance remains unsuspected

Though it is often useful in any medical history to record the chief complaint exactly as given by the patient this frequently is not the case with dermatologic patients A term such as rash is obviously noninformative and patients often describe their diseases in very colloquial terms Symptoms such as pruritus or pain vary so greatly with skin lesions that often they are not helpful It may be useful therefore to delay putting down the chief complaint until after the initial inspection The initial summary of the complaint should include data on the chief type or types of lesions whether they are localized or diffuse whether the dermatosis is acute or chronic and whether it is associated with symptoms or signs indicative of systemic disease

It is also very useful to record early in the history whether or not any *topical or systemic therapy* has been used and if so what because reactions to such medicaments are very common and frequently greatly obscure the underlying disease It is important to know whether *ultraviolet therapy* has been used whether this produced an exacerbation or improvement and whether any type of *ionizing radiation* or *corticosteroid* therapy has been employed

Otherwise the objectives of medical history in a patient with a disease affecting the skin are precisely the same as those of any other medical history namely to trace the development of the disease as accurately as possible to determine those elements of the patient s past history which may be related to the disease in question and those which are not to establish the relation of the patient and his disease to his heredity personal and occupational environment psychic and emotional status and previous medical care and to establish a good physician patient relationship by an attitude of kindly interest and willingness to listen In many patients who are seen because of a localized process such as a wart or seborrheic keratosis there will understandably be some resistance to extensive questioning and examination However particularly in patients of middle age or above requestioning may reveal that the patient has neglected himself medically and a few simple inquiries regarding the patient s general physical state and emphasis on the value of preventive health examinations may prove highly rewarding The author has had numerous occasions to direct such patients to appropriate general medical care through the small wedge of a banal skin lesion Many patients are curiously enough far more inclined to seek attention for what may be a very minor visible lesion on the skin than for the vague symptoms of more serious conditions

Family History It is obviously of importance in patients with dermatoses which appear to be allergic to inquire concerning allergic manifestations in blood relatives It is necessary that the more common allergic diseases such as hives eczema hay fever and asthma be mentioned specifically Other skin diseases in which a familial trend is frequent include ichthyosis acne baldness rosacea and psoriasis Occasionally skin tumors such as seborrheic keratoses may be strongly familial Less common conditions such as neurofibromatosis epiloia (neurocutaneous syndrome) and encephalotrigeminal angiomatosis may be genetically endowed Disturbances of pigmentation are common in families as is hereditary hemorrhagic telangiectasia (Rendu Osler Weber disease) Benign or juvenile acanthosis nigricans frequently has a high family incidence Many other examples could be cited but most of them are uncommon or rare

Age as a Factor in Diagnosis As with many other diseases certain groups of skin conditions are seen much more frequently in certain age groups Nevertheless great caution should be exercised and age alone should not be allowed to become a determining factor in arriving at a diagnosis This is particularly true of tumors The incidence of cancer of the skin increases with age but it is by no means rare in children (with the exception of malignant melanoma) and is moderately common in young adults Acne reaches its height in adolescence and rosacea in middle age but these conditions are not entirely confined to these age groups Atrophy of the skin and keratoses are characteristic of senility but they occur in young adults who are sensitive to sunlight and even in children (xeroderma pigmentosum) Atopic dermatitis frequently shows an age periodicity and is fortunately not common after late adolescence nevertheless it can persist indefinitely in severe or restricted forms The common types of ringworm of the scalp are seen entirely in children but an adult form has become endemic in the Southwest and Western United States Older individuals are less likely to have severe contact sensitization reactions in the skin and frequently become less troubled by sensitivities such as that to poison ivy Aside from tumors perhaps the single most important consideration of

to tumors as well Considerable confusion exists regarding the term *tumor* which is ordinarily used to designate the larger and deeper circumscribed infiltration of the skin or subcutaneous tissue However it is commonly used to describe lesions which are neoplastic regardless of size or location

The majority of papular eruptions may be diagnosed accurately by clinical examination and appropriate laboratory studies but in those which cannot be classified accurately biopsy is usually mandatory The histologic characteristics are by and large clear cut The most common dermatologic syndromes characterized by papules are tumors psoriasis lichen planus viral infections such as warts and molluscum contagiosum some drug eruptions xanthoma and certain lymphomas though there are many others The initial lesions of smallpox may be papular and secondary syphilis is frequently so The presence of atrophy or frank scarring immediately narrows the diagnostic considerations uncomplicated psoriasis for instance never produces scarring

Wheals (hives) are special types of papules They may remain as small individual lesions but frequently enlarge to form large plaques often with striking geographic outlines or may produce marked swelling of the face or an extremity (angioedema) Acute urticaria is most commonly produced by foods drugs and insect bites The cause of chronic recurrent urticaria is usually difficult to determine psychosomatic influences undoubtedly play a role Wheals are frequently a component of the eruption of erythema multiforme Wheals ordinarily respond to antihistaminics though large doses may be necessary Corticosteroid therapy is usually promptly effective though the lesions recur quickly often in more severe form if such treatment is discontinued without removal of the primary etiologic factor

VESICLES AND BULLAE These are sharply circumscribed collections of free fluid in the skin principally in the outer layers The most common representatives of vesicular dermatoses are contact dermatitis dyshidrosis of the hands and feet and herpes simplex In most instances the principal etiologic factor is readily determinable Bullae which are simply large vesicles represent a very vigorous effort of the skin to counteract some noxious agent Lesions may be bullous in a severe reaction to a contact allergen and of course chemical irritants or physical agents frequently produce a bullous reaction Under such circumstances the cause is ordinarily readily apparent In very extensive or chronic bullous eruptions thorough study is indicated The more important diseases characterized by bullous lesions are pemphigus dermatitis herpetiformis erythema multiforme (Stevens Johnson type) Bullae do not occur in psoriasis in most types of dermatitis other than reactions to contactants or drug eruptions or in acquired syphilis in the adult.

PUSTULES Pustules are simply circumscribed collections of free pus i e very superficial abscesses of the skin Dermatoses showing both vesicles and pustules are very common and vesicles frequently become pustular even in the absence of overt bacterial infection Pustular lesions of the skin cover a very wide range of conditions In pustular eruptions of more than a few days duration pathogenic bacteria are frequently culturable but it must not be assumed from this that all such organisms are necessarily acting as etiologic agents in the eruption

The above are the principal initial lesions of diseases affecting the skin

Other lesions which represent sequential or evolutionary changes are

SCALES These are simply accumulations of loose horny fragments of stratum corneum Certain types of scales are quite characteristic e g the greasy rather yellowish scales of chronic seborrheic dermatitis or the silvery piled up scales of psoriasis The chemical characteristics of scales vary considerably in different processes e g it is possible to make a diagnosis of psoriasis in some instances by simple chemical tests of the scales Such methods have not reached a level which is generally practical but as knowledge of the normal and pathologic biochemistry of the skin increases it should furnish aid in the diagnosis of obscure conditions

CRUSTS (SCABS) These are the dried remains of exudate from oozing erosive or ulcerated skin lesions They may consist of dried blood serum pus or an admixture Unless the diagnosis of a particular dermatosis is readily apparent representative crusts should always be removed to see what lies underneath One of the most characteristic of all crusts is that seen in diphtheria cutis which produces a covering tenacious and adherent unlike that seen in other bacterial infections

ULCERS Since ulcers represent a destructive process of the skin they always require explanation They may vary from small superficial erosions which heal without perceptible scarring to deep sometimes widespread lesions which involve underlying tissues or even adjacent bone If the etiologic factor concerned is not readily apparent such lesions deserve the most thorough study The factors concerned may sometimes be multiple and obscure

SCARS Scars may of course follow ulcers or may result from conditions in which there is no true ulceration e g discoid lupus atrophic lichen planus stasis or circumscribed scleroderma As with ulcers if the cause of the scarring is not apparent thorough and searching study from all standpoints is indicated The differentiation between tempo-

mental factors require no consideration In easily recognizable form they manifest themselves in the calloused hands of the workman the whealing of the skin in a patient with dermographism the characteristic patch of pigmented thickened skin on the neck which marks the violin player the keratoses and skin cancers which may mark the sailor long home from the sea the bullous reactions to trauma occurring in patients with epidermolysis bullosa the fungous infections as a penalty for wearing shoes and the dermatitic reactions to innumerable sensitizing and irritating occupational contactants This list of environmental excitants of cutaneous disease can be extended to include hundreds of examples

Clinical Examination

Inspection of the skin and mucous membranes is the simplest of all the procedures of physical examination Adequate exposure proper illumination good vision and thoroughness are essential Certain sites such as the scalp the folds of the skin the buccal mucous membranes (not just the pharynx) the palms and soles the anogenital region and the vaginal membranes are often not examined Gross diagnostic errors may result solely from insufficient illumination In obsolescent hospital wards and clinic quarters the natural or artificial illumination available is frequently unsatisfactory A flashlight or for that matter almost any small bulb source of illumination is entirely inadequate The physician places himself at a serious disadvantage if he makes a dermatologic examination with light sources which are glaring or produce distorted shadows Natural daylight without glare is the best source of illumination for general inspection of the skin An ordinary stand lamp with at least a 60 watt bulb is also very satisfactory In offices or clinics a wall bracket which permits positioning of the bulb is a necessity if large numbers of examinations are being done Fluorescent lighting is generally unsatisfactory because of flickering and color distortion Certain special surgical type lamps produce a superb shadowless nonglaring illumination of the skin The routine use of a hand lens or a head loop is essential for the adequate interpretation of many small lesions of the skin especially tumors

Diagnosis on the Basis of Presenting Skin Lesions The diagnosis of a disease affecting the skin often depends upon accurate classification of the individual lesions In diseases in which only the skin is involved where there is no systemic disturbance and no specific information obtainable by laboratory studies the morphologic characteristics furnish the only diagnostic clues It is therefore important that they be described accurately This can be done in straightforward simple terms there is no need to use an obsolescent or esoteric terminology The essential facts to be noted are

1 Distribution of the lesions
2 Physical characteristics
   a Flat raised or containing fluid (serous purulent or sanguineous)
   b Size shape and color
   c If palpable any special characteristics

Many conditions of the skin especially chronic ones present a variety of lesions With few exceptions however a skin disease in the individual patient is characterized initially by predominance of a single type of lesion which may be pathognomonic It is the mark of the expert in any field of medicine or surgery that he is able to sort out the presenting signs and symptoms in a complicated disorder and to determine which are representative of the underlying disease This faculty is particularly helpful in classifying diseases of the skin Among the debris of a chronic dermatosis the characteristic primary or initial lesion represents true diagnostic treasure From this it is ordinarily possible to determine the chain of secondary consequential lesions

This section outlines the various types of skin lesions with particular reference to systemic diseases in which they may occur No reference will be made to other parts of the examination but it is not intended to raise the classification of skin lesions to a stature more important than they deserve

MACULE A macule is simply a flat circumscribed *change in the color of the skin* The term ordinarily connotes lesions of relatively small size up to 1 or 2 cm in diameter More extensive changes in color are ordinarily referred to as patches or areas Macular processes are of three general types (1) due to extrinsically derived colored materials such as tattoo marks or imbedded material from lacerations or explosions (2) due to intrinsically derived pigment i e flat moles petechiae and hemorrhages or localized increase or decrease of melanin (3) erythematous reactions to a wide variety of pathogenic agents In the presence of constitutional symptoms or if there are purpuric changes in the lesion macules must be regarded as probable evidence of systemic disease Drug reactions are commonly macular and this possibility must always be considered

PAPULE Papules are circumscribed elevations of the skin varying roughly from a millimeter to a centimeter in size Larger infiltrated areas are often called plaques *Nodules* are circumscribed usually solid lesions which lie deeper in the skin or subcutaneous tissue The term is frequently applied to inflammatory processes e g erythema nodosum or subcutaneous fat necrosis but it may be applied

to tumors as well Considerable confusion exists regarding the term *tumor* which is ordinarily used to designate the larger and deeper circumscribed infiltration of the skin or subcutaneous tissue However it is commonly used to describe lesions which are neoplastic regardless of size or location

The majority of papular eruptions may be diagnosed accurately by clinical examination and appropriate laboratory studies but in those which cannot be classified accurately, biopsy is usually mandatory The histologic characteristics are by and large clear cut The most common dermatologic syndromes characterized by papules are tumors psoriasis lichen planus viral infections such as warts and moluscum contagiosum some drug eruptions xanthoma and certain lymphomas though there are many others The initial lesions of smallpox may be papular and secondary syphilis is frequently so The presence of atrophy or frank scarring immediately narrows the diagnostic considerations uncomplicated psoriasis for instance never produces scarring

Wheals (hives) are special types of papules They may remain as small individual lesions but frequently enlarge to form large plaques often with striking geographic outlines or may produce marked swelling of the face or an extremity (angioedema) Acute urticaria is most commonly produced by foods drugs and insect bites The cause of chronic recurrent urticaria is usually difficult to determine psychosomatic influences undoubtedly play a role Wheals are frequently a component of the *eruption of erythema multiforme* Wheals ordinarily respond to antihistaminics though large doses may be necessary Corticosteroid therapy is usually promptly effective though the lesions recur quickly often in more severe form if such treatment is discontinued without removal of the primary etiologic factor

VESICLES AND BULLAE These are sharply circumscribed collections of free fluid in the skin principally in the outer layers The most common representatives of vesicular dermatoses are contact dermatitis dyshidrosis of the hands and feet and herpes simplex In most instances the principal etiologic factor is readily determinable Bullae which are simply large vesicles represent a very vigorous effort of the skin to counteract some noxious agent Lesions may be bullous in a severe reaction to a contact allergen and of course chemical irritants or physical agents frequently produce a bullous reaction Under such circumstances the cause is ordinarily readily apparent In very extensive or chronic bullous eruptions thorough study is indicated The more important diseases characterized by bullous lesions are pemphigus dermatitis herpetiformis erythema multiforme (Stevens Johnson type) Bullae do not occur in psoriasis in most types of dermatitis other than reactions to contactants or drug eruptions or in acquired syphilis in the adult

PUSTULES Pustules are simply circumscribed collections of free pus i e very superficial abscesses of the skin Dermatoses showing both vesicles and pustules are very common and vesicles frequently become pustular even in the absence of overt bacterial infection Pustular lesions of the skin cover a very wide range of conditions In pustular eruptions of more than a few days duration pathogenic bacteria are frequently culturable but it must not be assumed from this that all such organisms are necessarily acting as etiologic agents in the eruption

The above are the principal initial lesions of diseases affecting the skin

Other lesions which represent sequential or evolutionary changes are

SCALES These are simply accumulations of loose horny fragments of stratum corneum Certain types of scales are quite characteristic e g the greasy rather yellowish scales of chronic seborrheic dermatitis or the silvery piled up scales of psoriasis The chemical characteristics of scales vary considerably in different processes e g it is possible to make a diagnosis of psoriasis in some instances by simple chemical tests of the scales Such methods have not reached a level which is generally practical but as knowledge of the normal and pathologic biochemistry of the skin increases it should furnish aid in the diagnosis of obscure conditions

CRUSTS (SCABS) *These are the dried remains of* exudate from oozing erosive or ulcerated skin lesions They may consist of dried blood serum pus or an admixture Unless the diagnosis of a particular dermatosis is readily apparent representative crusts should always be removed to see what lies underneath One of the most characteristic of all crusts is that seen in diphtheria cutis which produces a covering tenacious and adherent unlike that seen in other bacterial infections

ULCERS Since ulcers represent a destructive process of the skin they always require explanation They may vary from small superficial erosions which heal without perceptible scarring to deep sometimes widespread lesions which involve underlying tissues or even adjacent bone If the etiologic factor concerned is not readily apparent such lesions deserve the most thorough *study The factors con*cerned may sometimes be multiple and obscure

SCARS Scars may of course follow ulcers or may result from conditions in which there is no true ulceration e g discoid lupus atrophic lichen planus stasis or circumscribed scleroderma As with ulcers if the cause of the scarring is not apparent thorough and searching study from all standpoints is indicated The differentiation between tempo-

rarily hypertrophic scars and keloids is sometimes difficult to make temporary hypertrophy and elevation of scars after injury is by no means uncommon and may persist for several months Scars are frequently slightly painful or itchy Scars from ionizing irradiation are particularly vulnerable to trauma of all types especially sunlight Extensive scars from whatever cause but most particularly thermal burns tuberculosis and x ray therapy are prone to malignant changes

Configuration of Lesions Three characteristics of the configuration or arrangement of multiple lesions have considerable usefulness They are

GROUPING Characteristic grouped aggregations of vesicles occur in herpes simplex zoster and dermatitis herpetiformis Id reactions in the skin to infections are sometimes grouped i e in tuberculids or dermatophytids The multicentric foci of epithelioma (*in situ* type) are frequently grouped and gradually coalesce to form a single tumor plaque

ANNULARITY This is a striking feature of many dermatoses and reactions to systemic disease Pityriasis rosea lichen planus superficial ringworm infections bacterial infections urticaria erythema multiforme sarcoidosis discoid lupus syphilis deep fungous infections and other processes may produce rather characteristic annular lesions

LINEARITY A linear arrangement of individual lesions may come about as part of the basic pattern of the disease as in localized scleroderma linear nevi and even herpes zoster In some diseases the skin reacts to trauma in a characteristic linear pattern as in lichen planus and psoriasis Scars and keloids are frequently linear Viral infections such as warts may be inoculated in the skin by a scratch

THE PRIMARY INOCULATION OR CHANCRE COMPLEX The association of a lesion at the site of inoculation with regional adenopathy or with a more or less linear development of subsequent lesions is most commonly seen in acute bacterial infections (see p 907) Syphilis produces the best known of all the chancre complexes but this reaction is now observed rarely Primary inoculations of tuberculosis and certain deep fungous infections such as blastomycosis sporotrichosis and coccidioidomycosis may follow a pattern of development of an inflammatory papule and ulcer at the site of inoculation Regional adenopathy and the later development of inflammatory lesions along the areas of lymphatic drainage may occur The recognition of such a mode of reaction is important in the case of tuberculosis or the deep fungous infections as distinguished from spread of the lesions to the skin from a visceral focus because the resistance displayed to the infection after inoculation in the skin is often very high and such infections are usually self limited

Distribution Patterns of Skin Lesions In some diseases the pattern of distribution of skin lesions over the body is so characteristic as to be almost pathognomonic in others while one distribution pattern may be most characteristic variations from it are frequent The following are diseases which tend to involve certain sites

ACNE Since acne is a disease in which the follicular orifices and sebaceous glands are affected the lesions are concentrated in areas where these structures are most abundant large and active The face is the most frequently involved site but lesions appear on the shoulders chest upper back neck and upper arms in more extensive forms of the disease The lack of involvement of the scalp is striking even in the most severe cases only the scalp margins are invaded An even more extensive distribution may be seen in so called tropical acne in which the entire trunk may be affected with lesions on the buttocks and thighs as well

ROSACEA The lesions of rosacea occur in a highly characteristic pattern In severe and long standing examples diffuse involvement of the face may be noted but the flush areas are the sites affected initially These are the malar prominences the nose the forehead and point of the chin Rosacea is often seen in middle aged persons who have had acne in adolescence There is frequently an associated seborrheic dermatitis In the more severe forms pustules are common but these do not characteristically derive from blackheads as does acne The differentiation of rosacea from discoid lupus or systemic L E is ordinarily easily made though of course the two conditions may coexist The eyes should always be examined in rosacea however mild because of the infrequent but severe complication of rosacea keratitis

SEBORRHEIC DERMATITIS This is a third member of the common triad with acne and rosacea In seborrheic dermatitis of moderate severity the scalp may be the only site involved but the following areas are affected in approximate order of frequency in more extensive cases eyebrows skin above the bridge of the nose sides of the nose ears (especially the external auditory canals and retroauricular region) presternal and interscapular areas eyelid margins (a frequent source of chronic blepharitis) intertriginous areas on any part of the body especially the axillas the anogenital region and under the breasts in women The skin of the involved areas is peculiarly susceptible to acute or chronic secondary bacterial infection the intertriginous areas of the toes are rarely involved

PSORIASIS A tendency to involve the scalp knees elbows and back is characteristic of at least 75 per cent of all cases of psoriasis The most common alternate distribution of psoriasis is to the seborrheic areas Psoriasis is frequently misdiagnosed because

of a failure to examine the skin carefully and to determine the presence of lesions elsewhere This is likely if there is involvement of the nails (which is common in psoriasis) in which the condition may be wrongly diagnosed as a fungous infection if there is involvement of the feet and hands there may be confusion with ringworm infections and with syphilis if there is involvement of the genitalia it may be taken for moniliasis

PITYRIASIS ROSEA The individual lesion of pityriasis rosea is annular and ovoid often with a slight border and a characteristic narrow band of moderate scaling just inside this border In the efflorescence which follows the appearance of the primary or mother plaque the lesions tend to involve principally the trunk and upper portions of the extremities with the long axis of the lesions strikingly arranged along the lines of cleavage Even in examples of the disease in which the lesions themselves are unusual namely urticarial or more inflammatory this distribution pattern still holds The most common alternate distribution is a tendency for the lesions to occur distally on the extremities with relative absence of involvement of the trunk Pityriasis rosea may involve the neck but rarely the face It is a banal disease though sometimes very worrisome to the patient The course is that of a low grade infection though a causative organism has never been found Second attacks occur in no more than one per cent of patients Treatment is usually not necessary but if the lesions are extensive inflammatory and pruritic corticosteroid therapy for 3 to 4 days will usually give prompt relief

SCABIES The female *Acarus* prefers the following sites for her burrows the interdigital spaces of the fingers the palms the flexor surface of the wrists the axillary folds along the belt line the buttocks the genitalia in men and about the areola of the breasts in women The head is almost never involved in adults

ATOPIC DERMATITIS (DISSEMINATED NEURODERMATITIS) The objective changes in this very chronic disease are principally the result of rubbing and excoriation they involve the face neck antecubital spaces popliteal fossae wrists and thighs The condition commonly disappears after age twenty five but sometimes persists in a more localized form such as a chronic dermatitis of the hands

CONTACT DERMATITIS Reaction of the skin to external agents which includes primary chemical irritant effects and true sensitization reactions has a characteristic distribution involving the exposed sites in the case of industrial contactants plants and air borne pollens and chemicals

LICHEN PLANUS This chronic and pruritic disease is of little systemic significance The milder forms involve the buccal surfaces of the cheek the genitalia the flexor surfaces of the wrists and the trunk In the hypertrophic form the most marked lesions may be found on the lower legs this is the usual location of the lichen planus like lesions of Atabrine dermatitis

There are of course many other diseases with more or less characteristic patterns of distribution

Laboratory Methods of Dermatologic Diagnosis

The laboratory aids used in general medicine are helpful in arriving at a diagnosis of a disease affecting the skin Several special methods are useful

Biopsy Biopsy is an essential procedure in almost all chronic dermatoses in all pigmented lesions which are excised and in all lesions where there is a possibility of malignant change or serious systemic disease The diagnosis of some lesions will require the services of a pathologist with special training in dermatopathology Others present a clear cut pathognomonic picture and are easily diagnosed by the general pathologist A process involving the skin is seldom static The skin is not bathed in a homeostatic milieu as are internal organs it is subjected to numerous external influences which may disguise the primary process It is the responsibility of the clinician to exercise care and judgment in the selection of the lesion to be examined in determining which technique shall be used in obtaining the biopsy and in providing an informative protocol The specimen should be typical of the process and least subject to secondary trauma Generally this is the most recently evolved lesion Occasionally more than one biopsy may be required before the exact nature of a disease can be determined Multiple biopsies may be needed in large lesions such as chronic ulcers evolving at the site of an old burn or in granuloma inguinale

While consideration should be given to the cosmetic results in the procedure it must be emphasized that an inadequate biopsy specimen benefits neither the pathologist the physician nor the patient The most satisfactory procedure is removal of small lesions *in toto* (excision biopsy) and with larger lesions the removal of an elliptic specimen with its long axis through and at right angles to the border of the lesion In selected instances a 2 mm punch may provide adequate information and leave only a small inconsequential scar (see Fig 204) A 5 mm biopsy punch is sometimes required Bleeding may be stopped by pressure and the application of a small disk of gel foam or by electrodesiccation The scar from this procedure is small and tends to contract and become more linear in the course of time

The Tzanck Test Cytologic examination of the roof of a fresh bulla is useful in determining whether or not the process is pemphigus The

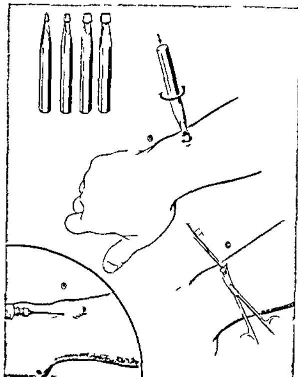

FIG 204 Punch biopsy This is a useful method for obtaining tissue from lesions in which complete excision is not feasible or when multiple biopsies may be desirable The removal should extend to the subcutaneous fat Punches of various diameters 2 to 8 mm are shown (*Pillsbury D M W B Shelley and A M Kligman "Dermatology* p 1331 *Philadelphia W B Saunders Company* 1956)

youngest vesicular lesion present is swabbed with an alcohol sponge the vesicle roof split with a scalpel and the fluid sponged away with dry gauze After the walls of the vesicle are reflected the base of the lesion is scraped gently with a scalpel to remove the basal epidermal cells The whitish material is smeared onto a clean glass slide dried in air fixed in methyl alcohol and stained with a routine Giemsa stain It can be mounted in balsam or examined directly after application of immersion oil to clear the cells In pemphigus one sees numerous small round epithelial cells many in isolated form No prickle cells are seen and there is a basic acantholysis The nucleus is large in relation to the cytoplasm which may be condensed in a basophilic peripheral ring

The Evaluation of Pigmented Nevi

It may be stated at the outset that it is impossible to examine any single pigmented nevus and state positively that it will *never* undergo a malignant change On the other hand it is neither feasible nor justifiable to undertake wholesale excision of pigmented moles some degree of clinical judgment must be exercised

Pigmented nevi are often not manifest at birth but characteristically develop during infancy and childhood and a few do not appear until adulthood Nevi first appear as macules These lesions are ordinarily of two histologic types (1) those in which the skin appears normal histologically except for increased deposition of melanin and a greater number of melanocytes at the *epidermal dermal junction* and (2) lesions which show clumps or aggregations of nevus cells apparently "dropping off or being extruded from the epidermal dermal junction into the underlying corium The first type is known as an *inactive junction nevus* the second may be active or inactive As the child becomes older these macules may become thickened and slightly elevated and the histologic picture changes with cords or bands of nevus cells becoming aggregated in the corium This lesion is called a compound nevus *part epidermal and part dermal* With the further passage of time more elevation of the lesion occurs and the nevus cells aggregate *entirely within the corium* This is the intradermal nevus a mature lesion which is almost always benign

In children a pigmented nevus can evolve rapidly with cellular features of hyperplasia and anaplasia resembling a malignant melanoma of the adult To this lesion the term *juvenile melanoma* has been applied However true malignant melanomas are so rare in childhood that it is often justifiable to delay decision about removal of a suspicious nevus until puberty

The presence of pigment alone does not indicate that a papule or tumor of the skin is a melanocytic nevus Certain entirely unrelated tumors many of them benign may show marked hyperpigmentation The seborrheic keratosis or wart a very common lesion is the best example of this Histiocytoma a common fibromatous lesion arising from the corium (seen on the lower legs of women) may also be pigmented Senile or actinic keratoses are sometimes dark and *pigmentation is frequent in* basal cell epitheliomas (see Fig 205)

Flat Lesions These are simply macular pigmented spots On histologic examination they show junctional activity in over two thirds of instances In such lesions *even pigmentation* and *sharp definition* of the border are reassuring In adults a very high proportion of such lesions will prove to be lentigines and of little significance in regard to potential malignancy However *if the pigmentation becomes speckled and the border more hazy and irregular* the odds are in favor of junctional activity and the lesion must be regarded with suspicion

Slightly Elevated Lesions Such moles are intermediate *between flat pigmented and those* which are raised above the surface of surrounding skin The lesion is clearly palpable Most will prove to be compound nevi and will give some evidence

of junctional activity Many of them particularly in younger patients will evolve in time into "pure" intradermal nevi They need not be excised routinely

Nevi with Pigmented Halo These are ordinarily slightly elevated lesions the base of which is surrounded by a flat pigmented ring with a border that is sometimes irregular These lesions are very likely to show junctional activity and should be adequately excised

Verrucoid Lesions Pigmented nevi with a markedly verrucose surface are raised and often very dark Some three fourths of such lesions show histologic evidence of junctional activity while the rest are intradermal

Raised nevi take other forms these include lesions with a polyploid or raspberry like surface a dome-shaped flat lesion a lesion attached to the skin by a thick pedicle and lesions definitely papillomatous sometimes attached only by a thin stalk These four types of lesions tend to be of the intradermal type and need not be excised unless definite changes are noted in them

Certain general considerations in the assessment of nevi apply to all morphologic types A *sudden change in the pigmentation* either to more marked pigmentation to splotchy irregular character or to fuzziness at the border of the lesion must be regarded with suspicion particularly in flat lesions However it must be kept in mind that melanocytic nevi show variations in pigment at puberty and during pregnancy and to some degree after exposure to sunlight

The presence of fully developed stiff hairs in the nevus is a reassuring sign While it is not an absolute dictum that hairy moles do not precede melanocarcinoma it can be said that they rarely do Such lesions are often frequently traumatized by repeated pulling of the hair or during shaving We have never observed an instance of melanoma arising from such a lesion though there are isolated reports of this

Changes in Size *A significant change in size* of a pigmented nevus in adults must almost always be regarded as a basis for excision The one exception to this is the common occurrence of acute or chronic follicular infection in hairy nevi with the development of tenderness and swelling Such inflammatory changes are no cause for alarm but if the mole becomes repeatedly infected excision is advisable

Ulceration and/or bleeding of previously quiescent moles are two signs of melanocarcinoma which are most commonly mentioned in cancer propaganda However these are late changes and it is essential to recognize the more subtle prodromal changes in moles if melanocarcinoma is to be controlled

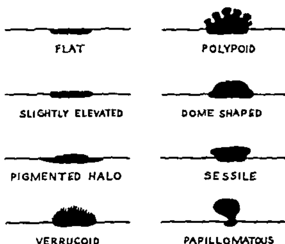

FIG 205 Various morphologic patterns in pigmented nevi The lesions in the left column are in general more likely to be junction nevi. (*After Shaffer B A.M.A Arch Dermatol* 72 120–132 1955)

Pigmented Lesions of the Mucous Membranes Melanocytic nevi may involve the stratified epithelium of the mouth and mucocutaneous junction of the anus Such lesions are usually flat and may be exceedingly difficult to interpret clinically The decision is often crucial because melanocarcinoma arising in the mucous membranes is rarely cured Pigmentation of the mouth in Negroes is common and is ordinarily blotchy and fairly diffuse Hyperpigmentation from chronic irritation e g along the bite margin is also common and need not be a cause for worry In the Peutz Jeghers syndrome pigmented macules of the mouth lips and/or digits may be associated with intestinal polyposis The most difficult lesions to interpret are freckles on the lips or dilated superficial blood vessels usually veins which are commonly blue black and may become sclerosed While these latter lesions are usually recognizable punch biopsy may occasionally be indicated

Special Cutaneous Disease Problems

Acne This is the classic stigma of adolescence almost a normal physiologic reaction in the skin The various clinical manifestations of acne have been designated by a variety of terms Most of these have little meaning or usefulness to non specialists but it is convenient to grade the severity of acne from I to IV as a guide in selecting the types of therapy which are most likely to be helpful Hereditary determinants condition the follicular orifice target organ" response yet fundamentally the excitant is hormonal At least 75 per cent of both sexes show some evidence of acne at the age of puberty There is no significant sex difference in incidence or severity

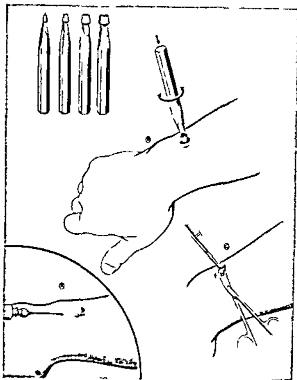

FIG 204 Punch biopsy *This is a useful method for* obtaining tissue from lesions in which complete excision is not feasible or when multiple biopsies may be desirable The removal should extend to the subcutaneous fat. Punches of various diameters 2 to 8 mm are shown (*Pillsbury D M W B Shelley and A M Kligman "Dermatology* p 1331 *Philadelphia W B Saunders Company* 1956)

youngest vesicular lesion present is swabbed with an alcohol sponge the vesicle roof split with a scalpel and the fluid sponged away with dry gauze After the walls of the vesicle are reflected the base of the lesion is scraped gently with a scalpel to remove the basal epidermal cells The whitish material is smeared onto a clean glass slide dried in air fixed in methyl alcohol and stained with a routine Giemsa stain It can be mounted in balsam *or examined directly after application of immersion* oil to clear the cells In pemphigus one sees numerous small round epithelial cells many in isolated form No prickle cells are seen and there is a basic acantholysis The nucleus is large in relation to the cytoplasm which may be condensed in a basophilic peripheral ring

The Evaluation of Pigmented Nevi

It may be stated at the outset that it is impossible to examine any single pigmented nevus and state positively that it will *never* undergo a malignant change On the other hand it is neither feasible nor justifiable to undertake wholesale excision of pigmented moles some degree of clinical judgment must be exercised

Pigmented nevi are often not manifest at birth but characteristically develop during infancy and childhood and a few do not appear until adulthood. Nevi first appear as macules These lesions are ordinarily of two histologic types (1) those in which the skin appears normal histologically except *for increased deposition of* melanin and a greater number of melanocytes at the *epidermal-dermal junction* and (2) lesions which show clumps or aggregations of nevus cells apparently "dropping off or being extruded from the epidermal-dermal junction into the underlying corium The first type is known as an *inactive junction nevus* the second may be active or inactive As the child becomes older these macules may become thickened and *slightly* elevated and the histologic picture changes with cords or bands of nevus cells becoming aggregated in the corium This lesion is called a compound nevus *part epidermal and part dermal* With the further passage of time more elevation of the lesion occurs and the nevus cells aggregate *entirely within the corium* This is the intradermal nevus a mature lesion which is almost always benign

In children a pigmented nevus can evolve rapidly with cellular features of hyperplasia and anaplasia resembling a malignant melanoma of the adult To this lesion the term *juvenile melanoma* has been applied However true malignant melanomas are so rare in childhood that it is often justifiable to delay decision about removal of a suspicious nevus until puberty

The presence of pigment alone does not indicate that a papule or tumor of the skin is a melanocytic nevus Certain entirely unrelated tumors many of them benign may show marked hyperpigmentation The seborrheic keratosis or wart a very common lesion is the best example of this Histiocytoma a common fibromatous lesion arising from the corium (seen on the lower legs of women) may also be pigmented Senile or actinic keratoses are sometimes dark and pigmentation is frequent in basal cell epitheliomas (see Fig 205)

Flat Lesions These are *simply* macular pigmented spots On histologic examination they show junctional activity in over two thirds of instances In such lesions *even pigmentation* and *sharp definition* of the border are reassuring In adults a very high proportion of such lesions will prove to be lentigines and of little significance in regard to potential malignancy However *if the pigmentation becomes speckled and the border more hazy and irregular* the odds are in favor of junctional activity and the lesion must be regarded with suspicion

Slightly Elevated Lesions Such moles are intermediate between flat pigmented and those which are raised above the surface of surrounding skin The lesion is clearly palpable Most will prove to be compound nevi and will give some evidence

inadequacies of previous treatment In so called tropical acne a very widespread and severe pustular eruption may develop on the face and entire trunk usually in persons who have had some evidence of acne previously but not infrequently in those in whom there has been no previous sign of the disease Treatment is futile until the patient can be placed in a cool dry environment

X RAY THERAPY The opinion expressed here on x ray therapy for acne is at variance with almost every textbook of dermatology or radiotherapy with which the author is familiar It is the author's belief that the value of such treatment has been greatly overrated but this is a controversial matter The author does not administer x ray therapy for acne

Acne was one of the first diseases of the skin for which x ray therapy was used Its popularity was based upon a supposed specific selective effect on the sebaceous glands The rather limited and surprisingly few controlled studies which have been done on the therapeutic effects of x ray therapy in acne have failed to demonstrate any immediate good effects with doses which may be regarded as comparatively safe in so far as late effects on the skin are concerned In these studies varying amounts of ionizing irradiation in divided doses have been administered to one side of the face while the other side was left untreated No difference in the progress of the acne of the two sides has been demonstrated

ACNE SCARRING The treatment of acne scars has long been considered unsatisfactory but the technique known as skin planing or surgical planing or dermabrasion is useful The most popular method involves freezing the skin with an ethyl chloride or Freon refrigerant spray followed by mechanical removal of the epidermis and upper dermis by means of a high speed rotary steel brush The epidermis then regenerates rapidly from the numerous pilosebaceous and sweat gland units which remain The rotating wire brush has almost completely replaced the sandpapering method formerly in vogue both because the technique is simpler and because of the occasional development of small foreign body granulomas from imbedded silicate granules after sandpapering

Superficial Fungous Infections (Ringworm)

The resident cutaneous flora is predominantly bacterial but a single fungous genus *Pityrosporum* with two species is also represented *P ovale* a yeastlike budding organism occurs in abundance in the scalp and in areas of high sebaceous gland activity but its etiologic relationship to dandruff or seborrheic dermatitis has never been proved *P orbiculare* while normally a skin resident may play a part in the development of the common banal disease tinea versicolor Saprophytic mold fungi are numerous in the atmosphere and spores contaminate the cutaneous surface more or less continuously For the most part they remain dormant on the skin but are problems in mycologic diagnostic work because of their tendency to overgrow culture plates Common weed fungi such as species of *Penicillium* and *Aspergillus* proliferate on diseased skin and have often been wrongly incriminated as the primary cause of cutaneous disease Weed fungi are particularly prone to colonize necrotic ulcers the inflamed ear canal and disease of the subungual skin but recovery of these fungi from such areas should not be interpreted as signifying pathogenicity

The importance of the superficial fungi as a cause of many cutaneous diseases has been considerably exaggerated and has led to many unnecessary reactions from treatment by irritating so called "fungicidal compounds" It is worthy of emphasis that inflammatory reactions on the feet are by no means always due to fungi and even if the pathogenic fungus is recovered this may be only a minor contributor to the inflammatory changes which may be present

The superficial ringworm infections may be divided into two main groups (1) the keratinolytic and (2) the nonkeratinolytic a miscellaneous group The distinctive property of the ringworm fungi is the possession of an enzyme which enables them to digest keratin With this biochemical equipment the nails can be disintegrated hair dissolved and the scaffolding of the stratum corneum the keratinized cells demolished The matrix of the hair and nails is not attacked nor the epidermis itself Except in unusual instances there is no tendency whatever for these fungi to invade living tissue nor has any toxin been isolated However sensitization to ringworm fungi may be induced This is seen most strikingly in inflammatory reactions occurring during the course of ringworm of the scalp or in some instances of acute inflammatory eruptions of the feet

The ringworm fungi or dermatophytes are divided among three genera *Trichophyton Microsporum* and *Epidermophyton* At least one pathogenic ringworm organism (*M gypseum*) has been repeatedly isolated from the soil which it presumably inhabits as a saprophyte By and large however human infections are contracted either from infected animals or from other human beings Certain species the so-called *anthropophilic organisms* show a distinct preference for human beings occurring rarely or not at all in animals The best example of this is the organism which commonly causes ringworm of the scalp especially in urban areas *M audouini* The *zoophilic ringworm* fungi

In some patients comedones may begin to develop at the age of nine or ten and if these patients are from a family stock in which acne has appeared frequently the outlook is disquieting The evidence of acne may persist for a variable period of time probably never less than a year but sometimes spanning the entire teens with extension well into the twenties The precise hormonal excitation of acne is not understood in complete detail ACTH injections in *susceptible individuals* of any age may produce acne Eunuchs do not develop the disease

The treatment of acne is not always satisfactory Although the hormonal stimulus is basic to the development of the disease there are no regularly effective means of combating it from this etiologic standpoint The routine administration of estrogenic hormones is illogical though there are selected cases in which a striking menstrual periodicity of the eruption seems to make such treatment advisable The therapeutic attack on acne must be on the fringes (1) local therapy which may help in relieving the plugging and rupture of the follicular orifice (2) control of contributing factors such as food or drugs (3) judicious drainage of purulent lesions by means which are least likely to produce scarring (4) combating infection with appropriate antibacterial measures and (5) taking advantage of natural aids such as sunlight as fully as possible None of these measures is curative in the strict sense all are palliative and serve only to keep the acne in check and to prevent undue scarring until the hormonal and sometimes emotional storm of adolescence has subsided

The treatments used for acne are extraordinarily numerous In assessing the value of some of them no particular attention seems to be paid to the associated factor of the passage of time in judging the true curative influence of a particular method There are some methods moreover such as stringent restrictions of diet the prolonged administration of antibacterial preparations and the use of x ray therapy which may have bad effects if employed overzealously and without good medical judgment

Preparations containing sulfur and resorcin are undoubtedly useful in mild acne particularly if the lesions are superficial They should be used to the point of producing a mild chapping effect Regular removal of comedones is helpful in some patients and with proper instruction may be done safely at home Drainage of frankly pustular lesions requires judgment It should not be done too early in the course of the lesion but may promote more rapid healing if performed when the nodule is fully fluctuant and the infection near the surface

The restriction of foods and drugs is important in many patients with acne but should not be done on any routine basis It can be shown without question that iodides bromides and Tridione make acne worse Foods such as chocolate nuts and coffee so frequently cause exacerbations as to make routine elimination justifiable From this point on it is advisable to individualize dietary elimination It should be kept in mind that in most patients with acne juvenile growth is rapid and energy output high so that dietary restrictions should be advised with care and good reason

Trauma to the skin may induce and perpetuate inflammatory acne lesions Constant pinching rubbing and picking of the face may become a subconscious habit and lead to much scarring because the acne lesions are not given a chance to heal spontaneously Violent traumatic exercise such as wrestling or football sometimes produces inflammatory acne lesions as does the rubbing of sweaters dirty sweat shirts or bacteria laden shoulder pads and other gear

In chronic severe acne in which there is unmistakable evidence of bacterial infection antibacterial therapy is often effective and justified As is the case with many chronic bacterial infections of the skin particularly if there is a tendency to formation of minute to larger abscesses within the skin such therapy must often be continued for long periods of time and should be initiated and supervised with good medical judgment Though penicillin is useful at times the incidence of acquired or potential allergic sensitivity to it is high Sulfonamide therapy is sometimes adequate but it may be necessary to employ broad spectrum antibiotics In general the drug should be given in full dosage initially to determine whether or not it will be effective following which the dose may be reduced to the lowest level which appears to keep the infection under control

Hormonal therapy of many types has been used in acne usually with indifferent results The routine administration of thyroid extract has long been a favorite treatment but the author is not convinced of its effectiveness Mention has been made of the occasional use of estrogenic hormones both topically and systemically Though such therapy may sometimes appear to be helpful it should be used on the basis of adequate endocrinologic study and supervision More recently the administration of corticosteroids systemically has enjoyed a considerable vogue In the author s experience there can be no question whatever that the anti inflammatory effect of such treatment on acne lesions may be marked sometimes with very small doses but the inherent physiologic risks of such therapy must be very carefully weighed against the fact that acne is a purely local disease with no systemic manifestations

Sunlight and vacation have a good effect in acne and may provide a striking demonstration of the

extend over the dorsum of the foot If the dorsal surface of the toes is involved a contact dermatitis from applied medication or from footgear should be suspected

During exacerbations of the vesicular type of ringworm infection the lesions frequently fuse and contain a yellowish gelatinous fluid Fungi are often not demonstrable at this phase because they are being cast off so rapidly Vesicles on the sole may be so deep as to appear papular and may not rupture spontaneously

The most chronic type of ringworm infection of the feet is caused by *T rubrum* This is frequently unilateral It is characterized by diffuse scaling often of a fine branny character by relative lack of inflammation and by extreme chronicity The process may become diffuse over the entire plantar surface and extend over the sides of the foot in a moccasin distribution The condition is sometimes difficult to differentiate from ichthyosis from a congenital keratosis or from psoriasis

Involvement of the toenails is almost inevitable in any long standing fungous infection of the feet This may be difficult to differentiate from the traumatic distortion which occurs inevitably in the toe nails of older persons particularly men Fungi are hard to isolate in scrapings taken from the nails because they are overshadowed by keratinous debris bacteria and molds It is probable that fungi in and under the nails are the chief source of what appear to be reinfections of other parts of the foot

TREATMENT Any experienced clinician who has seen many cases of ringworm of the feet must come to the conclusion that treatment frequently does more harm than good In particular it should be kept in mind that though hundreds of chemicals have antifungous effects in vitro no chemical which will be tolerated by the living skin is capable of killing fungi in hair nails or thick pieces of stratum corneum It is obviously unphysiologic to use compounds which are primary chemical irritants or which have sensitizing capacities The most effective methods of treatment are simple They include

1 *Dryness* This is the most important single factor especially in intertriginous involvement A patient with subacute or chronic ringworm should be most meticulous and careful about drying the toes after bathing It is helpful to do this with a dry crash washcloth with friction sufficient to remove scales and macerated skin The wearing of tight occlusive footgear should be avoided whenever possible and during warm weather the wearing of sandal type or aerated shoes is worthwhile If there is excessive perspiration the use of a nonabrasive foot powder is helpful it may be found advisable to change the socks once or twice daily Socks of an absorbent variety are best though they should not be too heavy during warm weather An elaborate ritual of boiling socks has no demonstrable value the sources of reinfection are numerous enough on the foot itself

2 *Rest* is helpful in the treatment of inflammation of the feet due to fungi In severe exacerbations bed rest may be essential In less severe forms the patient should restrict walking and athletic activity

The actual treatment of the infection is dependent upon the degree of inflammation In acute bullous exacerbations foot soaks of any bland solution either hot or cold are helpful Vesicles and bullae should be opened this may be done safely by the patient himself with a needle or with curved manicure scissors Tops of bullae should not be cut away completely because this exposes the underlying epidermis A shake lotion may be used sparingly to advantage and in this phase hydrocortisone in a lotion is often helpful Ointments should be used only after the process becomes less acute and should be applied at night rather than in the morning It is of particular importance that evidence of secondary bacterial infection be watched for For very severe acute attacks a short course of systemic corticosteroid therapy may be justified

In subacute or chronic types of fungous infection whether intertriginous vesicular or dry scaling type several preparations are useful The fatty acids are helpful and rarely cause irritation Castellani s paint is especially good for intertriginous areas and for patches of vesicles If there is thickened skin on the soles or macerated debris between the toes a preparation which will increase exfoliation should be prescribed Care must be taken however that it is not applied in a concentration which will produce damage Between the toes a preparation containing 3 per cent salicylic acid and 6 per cent benzoic acid in 70 per cent propyl alcohol is useful The same chemicals may be incorporated in an ointment type base yielding a half strength Whitfield ointment Some patients may find fatty acid ointments more helpful An alternate type of preparation is one containing salicylic acid and sulfur usually in a concentration of 2 or 3 per cent each *It is reemphasized that the treatment of superficial fungous infections of the skin is unsatisfactory in terms of a specific antifungous agent and that treatment should be directed toward making the conditions for the growth of the fungi less optimal toward allowing the skin to recover as rapidly as possible during acute exacerbations and toward assisting the skin to cast off the fungi which are present entirely in the stratum corneum or in the nails*

It has been suggested though on debatable evidence that the presence of a ringworm infection of the feet particularly that caused by *T rubrum*

on the other hand are frequent pathogens of domestic animals from which they may be transmitted to human beings The anthropophilic species have the clinical peculiarity of causing relatively noninflammatory and often very persistent types of ringworm while the zoophilic organisms tend to incite short lived inflammatory diseases in man

The transmissibility of ringworm infections has been greatly overrated It can be demonstrated regularly only in certain types of ringworm infections of the scalp occurring almost entirely in children In adults the transmission of the common types of ringworm infections of the feet groin and nails remains to a great extent a mystery It is difficult to produce an infection with superficial ringworm fungi experimentally in man regardless of the conditions of exposure It is a curious fact that ordinary ringworm infections of the feet though common in young men are relatively uncommon to rare in children in adult females and in the aged Familial infections with superficial ringworm fungi with the exception of tinea capitis are very uncommon This is in contrast to some other infections such as the virus of warts in which infection of all members of the family living together is sometimes observed

An important principle that provides much insight into certain peculiarities of the host parasite relationship in ringworm infections is that if superficial ringworm infections become markedly inflammatory there is a tendency toward spontaneous cure Marked inflammation is incompatible with the continued proliferation of the fungus because it is either desquamated along with other products in the wake of the inflammatory reaction or finds itself in an inhospitable environment owing to interference with normal keratin synthesis The success of the ringworm parasite in entrenching itself on the surface is dependent on its *not* provoking much reaction in the host This is particularly well seen in one of the most chronic of all common ringworm infections of adults that due to *Trichophyton rubrum* in which the inflammatory changes may be minimal but in which the infection once established may persist for many years On the other hand when the parasite injures the host to the point of provoking a significant tissue reaction it seals its own doom and the infection is almost always short lived This type of spontaneous cure is the basis for a clinical rule that such lesions should be treated conservatively Antifungous agents become superfluous and unnecessary the treatment is essentially that which might be applied to an acute or chronic dermatitic process of any type

In an inflammatory change affecting the skin in which a diagnosis of superficial ringworm is suspected there are three essential considerations

1 *Is a fungus present?* This may be determined easily by obtaining an adequate scraping from an active portion of the lesion and examination of the scales in a potassium hydroxide preparation Precise cultural identification of the fungus present is by no means always necessary to intelligent treatment though it is of value if the facilities for this are readily available

2 *Is the process acute subacute or chronic?* In the presence of an acute reaction the inflammatory changes will ordinarily subside spontaneously provided chemical or physical trauma to the affected skin is avoided In subacute or chronic ringworm infections nothing can be accomplished in terms of a compound which is specifically fungicidal in vivo there are no such compounds available The therapeutic attack must be by way of making conditions less favorable for the proliferation of the fungi by combating inflammation by assisting the exfoliation of infected skin and by preventing secondary bacterial invasion

3 *Are factors other than fungi contributing to the inflammatory changes seen?* Examples include excessive sweating and maceration primary irritations or sensitizations from applied medication and physical trauma from shoes or clothing

Ringworm of the Feet This is the most common type of ringworm infection and is largely a penalty for wearing shoes The majority of young American adult males acquire fungous infections of the feet the incidence being between 40 and 80 per cent The rate is highest in semitropical to tropical climates Fungous infections of the feet are extremely rare in children and are not common in adult females

The favorite sites of involvement in ringworm of the feet are the interdigital spaces especially the third and fourth the inner side of the arch, and the toenails Scaling is a constant feature of subacute or chronic fungous infections of the feet Inflammation in interdigital spaces may be variously caused by fungi by *Monilia* by simple maceration or may be due to psoriasis or some other disease of the skin If inflamed fissures are present secondary bacterial infection may be suspected The fungus most commonly cultured is *Trichophyton mentagrophytes* The intertriginous involvement may remain chronic and localized or may sometimes show acute exacerbations with the formation of vesicles and bullae extensively over the feet and with vesicular lesions elsewhere on the body particularly the hands ("id" reaction)

Ringworm infections of the feet may persist as occasional patches of vesicles which tend to localize on the instep portion of the sole and on the heel and ball of the foot In severe cases the entire sole may be involved The process does not commonly

duce the lesion called a *kerion* This has the appearance of a bacterial infection and in time involutes spontaneously with cure of the ringworm infection usually without permanent alopecia In ringworm of the scalp acquired by children from animals in which *M canis* is the most common causative organism the process is ordinarily inflammatory from the onset and is self limited

Ringworm of the scalp in children is a considerable public health problem and the incidence of the infection rises and falls in urban centers for reasons which are not readily apparent Treatment with antifungous agents is unavailing in terms of cure of the infection Involution occurs only if the infected hair shafts are cast off either as a result of inflammation developing around the hair follicles or through exposure to x rays in an amount which will produce temporary epilation Though the latter procedure in the hands of experts is reasonably safe it admittedly represents a rather drastic form of therapy It becomes essential in some instances however but the indications for the procedure should be very carefully considered

Various fungi are capable of producing chronic infection of the scalp in adults Favus caused by *T schoenleini* is relatively common in eastern Europe but is rare in the United States Another type of adult ringworm of the scalp that due to *T tonsurans* has long been seen with considerable frequency in Mexico and is being encountered increasingly in the Southwest United States and in California The condition resembles seborrheic dermatitis or psoriasis and there is usually moderate to marked loss of hair It cannot be detected easily because there is no fluorescence on Wood s light examination as is the case with almost all ringworm infections in childhood The proper diagnosis is made in most cases only if the clinical acuity of the examiner is high and if adequate mycologic studies are done

Pemphigus

Pemphigus is an uncommon relapsing disease which affects the mucocutaneous surface initially There are no signs of systemic disease at the onset but these soon develop secondarily Pemphigus is invariably fatal within a few months or years if adequate treatment is not instituted The disease is ordinarily controllable with corticoid therapy

The most common type of pemphigus (pemphigus vulgaris) is characterized by tense or flaccid bullae of varying size They appear without symptoms as a rule on skin or mucous membranes which had seemed entirely normal Occasional slight itching or burning may be noted The bullae rupture quite readily especially in the mouth pharynx and vagina leaving denuded areas These erosions or superficial ulcers are very slow to heal and often enlarge gradually When healing occurs no scarring results if there has not been secondary infection In some patients particularly those with brunet skins there may be marked residual hyperpigmentation

The distribution of lesions in pemphigus is variable though areas which are subject to rubbing pressure or stretching are more prone to develop lesions In pemphigus the epidermis readily detaches upon lateral tension and this phenomenon (Nikolsky s sign) may be demonstrated by drawing the finger over the surface of the skin with firm pressure The epidermis slides off much like a piece of wet tissue paper Though this sign is almost always present in pemphigus it may be seen in other bullous diseases as well e g epidermolysis bullosa and widespread bullous drug eruptions

The lesions of pemphigus usually involve the mucous membranes as well as the skin In many patients the initial lesions are entirely oral and/or vaginal The disease attacks adults of any age It is not seen in children and is rare during adolescence Members of the Jewish race are most commonly afflicted There is no sex predisposition

Secondary bacterial infection of the bullae or of denuded skin occurs commonly producing the rather characteristic mousy odor of the disease and frequently gives rise to septicemia which is a characteristic complication

Certain variations from the most common morphologic type of pemphigus occur

Pemphigus Foliaceus This is a rare member of the pemphigus group in which the lesions are predominantly those of exfoliative dermatitis Because of the very extensive cutaneous involvement signs of systemic disease may develop rapidly The disease begins with the appearance of small vesicles in which scaling and crusting develop producing a flaky surface similar to that seen in exfoliative dermatitis This is in contrast to the characteristic raw denuded areas seen in pemphigus vulgaris Slow symmetric spread of the lesions occurs and within a period of months the entire body may be covered with exfoliative lesions The hair and nails commonly are lost The histologic picture is characteristic The odor in exfoliative pemphigus is offensive The response of this form of pemphigus to corticosteroid therapy is less favorable than in common pemphigus

In *pemphigus vegetans* many of the bullous lesions are succeeded by hypertrophic vegetative masses in intertriginous areas such as the axillas groin and inframammary region These may later become dry and verrucose The vegetative lesions do not occur on the mucous membranes with the exception of the vermilion border of the lip and sometimes on the vulvar labia The lesions are malodorous and evidence of secondary bacterial infection is always present The process may sug

may induce peripheral vascular disease in the feet and lower legs The author is not convinced that this is true but in any event a ringworm infection of the feet becomes of increased importance in patients with peripheral vascular disease or with diabetes The scrupulousness of foot hygiene must be redoubled and particular care should be taken *not to use chemicals with possible cauterant effects* on the skin because a very slowly healing ulcer may result The services of a competent chiropodist are helpful to such patients not only from the standpoint of maintaining good foot hygiene but in an effort to remove irritation from toenails calluses and footgear

Majocchi's granuloma is a distinctive manifestation of ringworm infection in the form of a granulomatous folliculitis and perifolliculitis It occurs most frequently in women who shave their legs and who have a diffuse *T rubrum* infection of the feet Indefinite and rather indistinct scaling patches develop on the lower half of the lower leg and inflammatory nodules develop at the borders of these patches The nodules rarely exceed a centimeter in diameter and are flat or only slightly elevated If the lesion is observed early it may be seen to be centered by a hair The nodules are not pruritic and usually only slightly tender They do not progress to suppuration and persist as long as 3 or 4 months They may then become slowly absorbed or undergo necrosis and heal with a depressed scar Histopathologic examination reveals a characteristic foreign body granuloma degenerating fungous elements may be demonstrated by the Hotchkiss McManus method

Certain other puzzling conditions of the lower extremities are seen in association with fungous infections of the feet though the precise relation is difficult to establish One is an erysipelas like process of the lower extremities occurring in the form of a recurrent superficial cellulitis of brief duration and apparently representing an id reaction On the legs and elsewhere the following reaction patterns may be in some cases representative of an allergic sensitivity to ringworm (1) erythema nodosum (2) erythema multiforme (rare) and (3) indefinite macular rashes

Ringworm of the Nails When a superficial ringworm infection involves the toenails and/or fingernails topical therapy becomes quite useless Cure may sometimes be effected by removal of the nail plate and careful scraping away of all debris in the lateral gutters and in the nail base However this procedure is rarely successful in the toenails and is not advised Reinfection is usually prompt In fingernails successful cure of the ringworm infection by surgical avulsion is more frequent though probably less than 50 per cent It is more likely to be helpful if only one or two fingernails are involved and if there is not an extensive focus of ringworm infection on the skin of the hand Care must be taken not to confuse other nail dystrophies with a ringworm infection The most common of these are psoriasis chronic dermatitis of the distal phalanges chronic paronychial infection and arthritis involving the distal joint

Ringworm of the Groin This is a common affliction especially in males during the summer months The characteristic lesions are seen in the crural folds and the upper inner thigh usually with an annular scaling ring in the latter area Several other conditions may be confused particularly psoriasis and seborrheic dermatitis Anal and vulvar pruritus are not per se commonly due to fungi though *Candida* may sometimes play a role In tinea cruris it is particularly important not to use compounds which will produce any reaction because the male genitalia are very susceptible to irritation and a chronic dermatitis which is protracted by scratching may result

Ringworm of the Body Extensive ringworm infections of the trunk or extremities are uncommon in temperate climates though they are seen with some frequency in the tropics In the presence of a ring shaped moderately inflamed lesion the odds are generally in favor of some condition other than a *fungous infection e g pityriasis rosea seborrheic* dermatitis or psoriasis In those instances in which a proved extensive fungous infection of the skin of the trunk and extremities is observed in patients in temperate climates patients should be subjected to careful study for hematologic disease or diabetes

Ringworm of the Hands Though fungous infections of the hands are by no means rare this diagnosis is made with too great frequency The infection in this area has so much in common with infections of the feet that it need not be considered in any great detail There are two main types (1) the inflammatory vesicular and (2) the noninflammatory squamous The former is uncommon in temperate climates though dermatophytids associated with infections of the feet are common *Trichophyton mentagrophytes* is the organism usually recoverable from the acute vesicular type The course is one of spontaneous healing provided the hands are not subjected to constant chemical or traumatic irritation

Ringworm of the Scalp Tinea capitis is predominantly a disease of children and will not be considered in detail herein It is caused by a variety of fungi In cases which are transmitted from man to man and in which the most common causative organism is *Microsporum audouini* the course is one of great chronicity healing does not occur unless increased resistance of the host becomes evident in the form of inflammatory changes Such a local response may become quite severe and pro-

gest a fungating iododerma or bromoderma grossly or may even mimic the condylomas of secondary syphilis or the lesions of granuloma inguinale In this type as in exfoliative pemphigus the response to corticosteroid therapy may be poor and massive doses are often required

In another type of pemphigus not uncommon the distribution and morphology of the lesions is suggestive of a mixture of pemphigus seborrheic dermatitis and lupus erythematosus (Senear Usher syndrome) Erythematous scaling and crusted lesions develop on the nose and malar areas in a butterfly distribution and similar lesions with or without bullae may also appear on the anterior chest interscapular area and the scalp The mucous membranes show involvement only occasionally The general health of the patient is ordinarily good for some time after the onset of the disease The course of the eruption is insidious and slow but frank fatal pemphigus usually develops

Brazilian Pemphigus (Fogo Selvagem) This disease which is endemic in Brazil is clinically and *histologically identical with pemphigus foliaceus* The endemic nature of the disease makes it impossible to state with certainty that it is similar to pemphigus foliaceus since the latter has never been seen in endemic form in the United States or in Europe The best opinion would indicate that fogo selvagem is an infectious contagious disease About 3 000 cases are on record in Brazil and convincing evidence of transmission from person to person is available *The disease almost always begins before* the age of thirty is frequently associated with endocrine disturbances and does not involve the mucous membranes

Histologic Diagnosis The histologic features of common pemphigus are highly characteristic and the changes seen in smears or biopsies of early lesions are diagnostic There is a disturbance of the epidermal cells in which the fundamental change *is a disruption of the intercellular connections* of the epidermis (acantholysis) seen in either biopsies or material taken by a special scraping (see p 1743)

The course of pemphigus is variable The untreated patient may show occasional remissions but recurrences invariably develop each a little more severe than the previous one Death may occur from 2 to 3 months following the initial lesion or the disease may continue for years If corticosteroid therapy is not administered death within 2 years may be anticipated This occurs as a result of shock toxemia a cachectic state or some secondary complication such as septicemia or bronchopneumonia *It is important to keep in mind* that the skin and mucous membranes are the primary tissues involved and if these lesions can be controlled signs of systemic disease will remain absent or very moderate In uncontrolled pemphigus marked secondary anemia may develop Hypoalbuminemia may also be present because of the negative nitrogen balance resulting from loss of protein to denuded areas of skin and from *the inability of some patients to ingest* solid foods In widespread severe pemphigus the patients are extremely ill There may be a marked leukocytosis at times eosinophilia and the general picture is one of serious toxicity The temperature is ordinarily not markedly elevated unless extensive secondary bacterial infection has occurred Routine laboratory studies do not yield characteristic or constant findings However in advanced *cases the sedimentation rate is increased anemia is* constant the total serum proteins are almost invariably lowered and marked disturbance of serum electrolytes may be seen

Treatment Corticosteroid therapy is the only means by which true pemphigus may be controlled it is one of the few diseases in which such therapy is justified as soon as the diagnosis is established even though the presenting signs and symptoms are *mild Conditions which might ordinarily* be regarded as contraindications to corticosteroid therapy must often be waived if the diagnosis of pemphigus is established It is too early to suggest that actual cures of pemphigus have been achieved but considerable numbers of patients have been maintained in a state of remission for the several years since corticosteroid therapy became available As a rule such therapy must be continued indefinitely *very few patients have found it* possible to remain in remission in the absence of continued treatment

It is advisable to start treatment with rather large doses of corticosteroids the author prefers ACTH ordinarily in the gel form If the patient is critically ill ACTH in a dose of 25 to 40 units should be given daily by 8 hr intravenous drip In many patients subsidence of the eruption will be noted in a few days and reduction of the dose of corticotropin may then be possible ordinarily by lowering the daily dose to 15 to 20 units and then giving such a dose less frequently No set rules for this can be put down In some patients the dose may be reduced to a surprisingly low level as little as *10 or 15 units of ACTH every 2 weeks* If cortisone or its analogues are used the initial dose required may sometimes be so high as to be unfeasible economically However later in the course of treatment trial of such therapy may ordinarily be undertaken safely

The corollary medical and nursing care of extensive pemphigus is a formidable problem in some patients The supervision required is not dissimilar to that of an extensive burn and close check for evidence of local or systemic infection of protein and electrolyte balance and of the nutritional and hematologic status must be kept Blood transfusions

PLATE VI

(*Upper left*) Widespread mycosis fungoides This is the only lymphoma which produces characteristic skin lesions (*Upper right*) Leukemid eruption in a patient with rapidly fatal acute myelogenous leukemia This was the initial sign of illness The skin lesions showed no leukemic infiltrate (*Center left*) Severe seborrheic dermatitis with otiti e terna and secondary streptococcal infection (*Center right*) Longstanding blastomycosis The patient's general health was excellent (*Lower left*) Inflammatory tinea profunda (*Trichophyton mentagrophytes*) infection acquired from a co No systemic reaction The lesion involuted spontaneously (*Lower right*) Atopic dermatitis Involvement of the antecubital fossa and surrounding skin is characteristic The changes seen are almost entirely due to scratching and rubbing

PLATE V

(*Upper left*) Epidermoid carcinoma developing in scar of burn on lower leg. Any persistent ulcerative or proliferative process in a scar should be subjected to biopsy. (*Upper right*) Basal cell epithelioma. This is a relatively neglected lesion. Surgical excision was curative. (*Center left*) Chronic psoriasis and melanotic melanoma. In extensive chronic dermatoses the development of other significant unrelated skin lesions, particularly tumors, may easily go unnoted. (*Center right*) Severe bullous reaction to sulfathiazole. The lesions are very similar to those seen in pemphigus. This patient had been sensitized by previous prolonged topical sulfonamide therapy. (*Lower left*) Nodules of melanocarcinoma of scalp occurring around scar of previously excised nevus. Wide excision was not curative. (*Lower right*) Severe industrial contact dermatitis.

are sometimes of critical value If there is evidence of bacterial infection of the skin even in the absence of a systemic response it is rarely possible to control it by topical therapy *It is of the greatest importance* to conserve the accessible veins as much as possible because they may be few in number if the cutaneous lesions are extensive

Dermatitis and Eczema

Various types of acute and chronic dermatitis constitute over 50 per cent of all clinical dermatology While the changes in the skin follow a basic pattern which is reasonably constant the factors which may initiate or prolong a dermatitis are numerous

The morphologic changes of acute and chronic dermatitis are clear cut and not easy to confuse with other patterns of skin reactions The signs of dermatitis in the order of their evolution are as follows (1) erythema and swelling (2) oozing and/or vesiculation (3) crusting and scaling (4) thickening and evidence of repeated excoriation (5) hyperpigmentation scratch papule formation and lichenification The first three changes are those of an acute dermatitis the latter two are seen only if the process persists for several weeks or longer While there is no entirely satisfactory classification which will include all variants of a dermatitis eczema group of diseases some categorization is helpful Separate classification of a particular group is justified and helpful if one or more of the following criteria are satisfied (1) it is a type in which a definite cause can be determined (2) it occurs in a fairly regular pattern which (3) is helpful in determining the prognosis in the individual patient gives clear indication for certain types of treatments or indicates the need for further allergic and other medical studies The following main groups exist

Acute Contact Dermatitis In this type of dermatitis the change may be due either to primary irritation from toxic substances or to true allergic sensitization (see p 1162) Contact dermatitis is the prototype of all dermatitic reactions in the skin and by far the most satisfactory to manage therapeutically In a very high proportion of patients the responsible substance may be determined accurately and the cause removed It is essential that this be done as quickly as possible because persistence of the reaction will lead to trailing complications which may be self perpetuating

Atopic Dermatitis This exceedingly chronic dermatitis possesses distinctive features in respect to localization of lesions personal and familial evidence of allergy and a characteristic though often erratic course It produces more chronic disability than any other disease in which the chief manifestations are in the skin This plus the fact that the affected patient frequently has other evidences of atopy makes the disease of considerable medical importance In addition because corticosteroid therapy is often rapidly effective in relieving the inflammatory changes the problem of untoward physiologic effects arising from prolonged therapy of this type given for atopic dermatitis is assuming increasing importance Atopic dermatitis of and by itself is not a fatal disease but the suddenly developing complication of secondary infection by the virus of either herpes simplex or of vaccinia may sometimes lead to death

Seborrheic Dermatitis This form of dermatitis is also quite clear cut in respect to localization of lesions frequent association with evidence of sebaceous dysfunction increased vulnerability to secondary bacterial infection and a course which is often chronic In widespread forms it may be very disabling

Nummular Dermatitis This type of dermatitis has a distinctive morphologic pattern (nummular coinlike) The lesions are frankly dermatitic round and usually vary in size from 2 to 4 cm in diameter Low grade secondary infection is common The distribution is chiefly to the extensor surfaces of the extremities and the posterior shoulders and back though any site may be affected The dermatitis is most common in patients above middle age and may follow an acute contact dermatitis or occur as an id complication of chronic stasis dermatitis It is possibly seen more frequently in individuals with atopic backgrounds The causative factors are poorly understood but a psychosomatic component is often prominent The lesions commonly recur at the same site and the outlook for immediate cure of the disease is poor though permanent remission may ordinarily be anticipated eventually

Lichen Simplex Chronicus (Circumscribed Neurodermatitis) This is a clear cut and very common condition in which the changes are due almost *entirely to scratching and rubbing* The lesions are usually sharply circumscribed Any site may be affected but common ones are in the occipital region in women on the neck and on the lower legs Many cases of vulvar and anal pruritus fall into the group of circumscribed neurodermatitis The area involved becomes itchy either as a result of some preceding irritation or often without any previous lesion The scratch itch scratch cycle becomes firmly established Psychosomatic factors are often prominent and many patients frequently admit to indulging in scratching as a means of relieving nervous tension In such persons if the patch is not too troublesome such a lesion is probably to be preferred to some psychosomatic manifestation affecting another organ system

Stasis Dermatitis This is another clear cut type of dermatitis in which the basic etiologic factors are

scratching or from the application of skin irritants In atopic dermatitis a disease in which almost all of the changes in the skin are the result of excoriation and rubbing the antecubital area has a consistently increased sensitivity to itch stimuli while this is not the case in normal controls Continuation and elaboration of these studies gives promise of much better methods of evaluating the effectiveness of antipruritic agents and of understanding the variabilities of itching seen in the same disease occurring in different individuals

The remedies which are used for the relief of itching are legion In some of them a reasonable explanation of the mechanism of effectiveness is apparent while in others it is not The following statements may be made with some assurance

Topical agents whether local anesthetics or otherwise are least effective when the skin surface is relatively undamaged The absorption of local anesthetics from the skin is so minimal as to make it impossible to achieve adequate concentration in the underlying itch points If the integrity of the skin is disturbed there is some increase in effectiveness but it is still not as marked as might be desired Among the useful compounds are menthol and camphor Derivatives of Novocain are not advised because of their high sensitizing capacities most marked with Pontocaine Antihistaminics likewise have some local anesthetic properties but many of them are potent sensitizers and their clinical effectiveness on topical application is poor Topical agents for the relief of itching are much more effective on mucous membranes or at mucocutaneous junctions because of the significant absorption which will occur in these areas

In skin which is dry old or chapped very minor stimuli may induce paroxysms of itching Under such conditions a bland protective ointment or paste often has a good effect in preventing these stimuli from reaching the nerve endings Extremes of heat or cold likewise have some temporary good effect upon itching but should not be so drastically applied as to injure the skin

The antipruritic effects of topical steroid therapy e g hydrocortisone prednisone prednisolone are often marked particularly at mucocutaneous junctions so that such agents are very useful in vulvar and anal pruritus and in inflammatory conditions about the eyelids

The systemically administered compounds which will relieve itching are few The most striking of these are of course the steroids apparently acting through their antiinflammatory effects The physiologic risks of such therapy are such however as to make them justified only for very extensive and severe dermatologic processes They are probably most valuable and safe in short term conditions such as contact dermatitis or pruritic drug eruptions Antihistaminics are useful in frankly allergic conditions such as acute urticaria but have very limited effects in chronic dermatitis Tranquilizing agents such as *Rauwolfia* derivatives meprobamate and chlorpromazine may have moderate antipruritic effect in some patients but they are highly irregular in their effectiveness in this regard A phenothiazine compound trimeprazine has had wide investigational use in France and a limited application to date in the United States In the author s experience it has very marked antipruritic effects in some patients though its usefulness is somewhat limited by associated variable sedative effects In patients in whom topical therapy is ineffective and steroids are either unjustified or ineffective trimeprazine is well worthy of trial This is particularly true in infantile eczema atopic dermatitis and pruritus incident to diseases such as obstructive jaundice or Hodgkin s disease

Generalized Exfoliative Dermatitis

A chronic dermatosis which affects all or nearly all of the skin surface is a general medical problem of considerable importance and much difficulty Though examples of such conditions are seen in all age groups the incidence is highest in persons above middle age In some instances the early origins of the exfoliative dermatitis in terms of the type or etiology of the inflammatory changes are fairly clear Not infrequently however the generalized dermatitis arises for no apparent cause The changes may prove to be completely intractable especially in older patients

In the chronic phase of a generalized exfoliative process the skin is red thickened and scaling There may be oozing but vesicles are rarely seen A variety of disease conditions may give rise to this process It is fortunately very rare after acute contact dermatitis localized neurodermatitis nummular dermatitis and eruptions of the hands and feet Seborrheic dermatitis and atopic dermatitis may sometimes eventuate in a chronic exfoliative process Drugs may produce a chronic generalized reaction this was seen frequently when trivalent arsenical compounds were used in the treatment of syphilis Prolonged extensive contact with a sensitizing agent particularly an air borne one may occasionally induce an irreversible generalized dermatitis

Certain nevoid changes may produce chronic redness and exfoliation The most common of these are severe ichthyosis or congenital ichthyosiform erythroderma Psoriasis may at any age but most frequently in adults become completely generalized In this phase it is frequently accompanied by rheumatoid arthritic changes

In any patient with a generalized exfoliative process but particularly those above middle age

peripheral venous disease and tissue edema (see p 1339) It is important that prompt measures to control the dermatitis be undertaken before it has become severe and chronic Stasis dermatitis is characterized by greatly increased vulnerability to primary irritant or sensitization reactions to topical medication

These are the reasonably clear cut syndromes in the dermatitis eczema group There are three other well defined large groups as follows

Chronic Eczematous Dermatitis This is a group in which often the original cause and initial pattern of the disease have long been lost sight of and in which various secondary factors are playing a predominant role It is frequently the end point of a contact dermatitis in which the causative factor was not recognized promptly The extent and distribution of the dermatitis may vary greatly There are no constant associated systemic factors though sensitivity to particular foods or drugs must always be kept in mind In such patients there is temptation to use a wide variety of topical measures or to resort to systemic corticosteroid therapy without careful study of the patient as a whole and pains taking analysis of the various etiologic factors which might be playing a role including vasomotor disturbances sweating dysfunction low grade bacterial infection and psychosomatic factors

Infantile Eczema This is a classification based entirely on the age and the peculiarities of dermatitic reactions of the infantile skin These differ considerably from those of the adult

Chronic Dermatitis of Hands and/or Feet This is a classification based entirely upon the region involved but it is justified because it is such a common problem The etiologic factors are often complex Contact atopic and nummular dermatitis not infrequently are localized to the hands and feet Certain forms of psoriasis and of "id" reactions may appear in this fashion For all practical purposes superficial acute fungous infections may be included in this group This condition may be exceedingly chronic and at times highly disabling

Treatment of Pruritus

The means of relieving pruritus are on the whole much less satisfactory than those for the relief of pain In localized processes of acute nature the symptom is troublesome but relatively unimportant However in more extensive chronic inflammatory eruptions and in association with jaundice or with Hodgkin s disease the pruritus may be so severe and overpowering as to allow the patient to think of little else Though analgesics such as aspirin are of occasional small benefit potent analgesics such as morphine frequently increase itching apparently through the release of histamine from mast cells in the skin Sedatives and hypnotics may induce sleep in the patient but the itching continues unabated Much harm may result from poorly selected topical agents which produce irritation or sensitization e g phenol antihistaminics and compounds related to Novocain

Understanding of the phenomena of itching and the transmission of the itch stimulus has been greatly extended by the recent work of Shelley Arthur and others Until recently histamine was the standard material for inducing a measurable pruritus and this material was considered as the probable principal chemomediator of itching Shelley and Arthur postulated that an enzyme was concerned in the mediation of itching and have studied this intensively Severe itching may be induced by a wide variety of proteinases without the erythema and whealing seen following the injection of histamine Proteinases are available to the subepidermal cutaneous nerve endings from a wide variety of sources in cutaneous disease e g from infiltrates (leukopeptidases) from surface flora (fungous and bacterial proteinases) from the capillaries (plasmin) and from damaged epidermal cells (catheps ins) It has been shown that the antigen antibody reaction releases proteinases

The well established punctate nature of the cutaneous sensory system has been demonstrated to hold true for the itch receptors and itch points may be mapped on the skin either by chemical stimuli or by appropriate electrostimulation with microelectrodes The itch stimulus is transmitted at a conduction speed for the small unmyelinated slow (C) fibers Histologic examination of itch points shows them to consist of clumps of free unmyelinated nerve endings spread at a level just below the epidermis

On the basis of clinical observation it is well known that some diseases tend to produce pruritus while others do not some persons with itching diseases (i e lichen planus) itch while some do not itching tends to come and go often without any apparent relation to the morphologic changes in the skin while healing lesions frequently itch more than acute lesions

By the use of a standard itch stimulus Shelley and Arthur have shown that there is a marked variation in the itchiness of the skin of various parts of the body in the same patient and also considerable differences in the response of different subjects to the itch stimulus The hands are found to be a naturally itchy area though eczematous eruptions of the hands are characterized by remarkable variation in the amount of itching After acute exacerbations there is evidence that damage to the receptor nerve network has occurred On the basis of clinical observation it is apparent that the perianal and vulvar regions are also highly itchy and that this itching may be relieved temporarily by damage from

the possibility of a lymphoma must receive serious consideration Mycosis fungoides is frequently preceded prior to the development of frank skin tumors by a dry patchy dermatitis which with each recurrence becomes more severe and extensive Such lesions may recur for as long as a decade Repeated biopsies over a period of years may be required before the characteristic cellular infiltrate of mycosis fungoides is demonstrable

Senile involution of the skin may produce a severe and extensive erythroderma Such changes have been designated by a variety of terms based on morphologic variations but these are of little value to the general clinician The syndrome may be designated as *exfoliative erythroderma* and the patient then studied further for any dermatologic or general medical criteria which will provide a more useful and precise classification

Management Patients with generalized inflammatory exfoliative dermatoses deserve the most searching study They are often relatively or completely disabled and their appearance may bring about social ostracism

Biopsy of the skin often with repetition at intervals of weeks or months is an essential feature of the study of such patients The most careful hematologic studies are indicated In such patients varying degrees of generalized lymphadenopathy are almost always present either in response to the chronic inflammatory changes of the skin or as part of an underlying lymphoma Lymph node biopsy obviously will be required at times but should not be undertaken without due consideration because the healing after deep surgical biopsy is often very protracted especially in the inguinal or axillary regions Chemical studies of the blood with particular reference to serum protein levels and electrolytes may at times be revealing It is particularly important to keep in mind that the protein losses from exfoliation may be significant

The heat regulatory mechanisms of such patients are greatly disturbed A moderately cool environment may often induce a chill because of increased radiation from the vascular bed Because of the marked decrease in sweating which may be present sometimes amounting to complete anhidrosis increase in the environmental temperature is poorly tolerated and may induce febrile episodes

Skilled nursing care is of the utmost importance in such patients but may be a disagreeable and taxing task Topical therapy other than with very bland and inexpensive agents is not feasible As a rule petroleum or equal parts of water and Aquaphor or ordinary hydrogenated vegetable oils are best tolerated Care should be employed in the widespread use of compounds which may be toxic on absorption e g salicylic acid mercury phenol and strong concentrations of tar and resorcin

Systemic corticosteroid therapy is almost always indicated in patients with severe intractable exfoliative dermatitis but such therapy must sometimes be very prolonged In exfoliative psoriasis the author has found the steroid triamcinolone of considerable value in comparison with the steroids previously available Occasional transfusions of whole blood may be indicated Fever therapy by foreign protein injections is sometimes worthwhile The condition sometimes justifies a trial of x ray therapy preferably to a restricted portion of the skin initially This must be given with the greatest care and expertness however if extensive areas are to be exposed to ionizing radiation

Patients with generalized exfoliative dermatitis may be highly susceptible to infection of localized superficial type to cellulitis to deep cutaneous abscesses and to thrombophlebitis Intermittent or prolonged administration of appropriate antibiotics may be necessary

Section 1 General Problems

267 GENERAL CARE OF THE PATIENT

One of the first decisions to be made with regard to medical management is whether the care of the patient is to be undertaken at home or in the hospital and whether the services of special nurses will be required The answer to these questions will depend on a number of factors the economic circumstances of the patient the character of his illness the facilities that will probably be necessary in the investigation and management of the illness the nursing problems likely to be encountered and the capacity of the attending personnel to handle them as well as the personalities of the patient and of those surrounding him

Regardless of the competence and experience of nurses or others who may be in attendance the management of the illness should be in the firm charge of the physician It is the obligation of the doctor to write orders with regard to all relevant details in so unambiguous a manner as to provide no foreseeable opportunity for confusion frequency with which vital signs are to be noted and recorded diet fluid intake rest and activity administration of drugs care of skin and mouth in certain cases and other matters essential to the welfare and comfort of the patient

The family and nurses should be instructed regarding possible untoward events that may occur in the course of the illness or as the result of the administration of drugs or other forms of therapy This is important not only because prompt measures may be taken to counteract the harmful or disagreeable consequences but also because the patient and his family are less likely to be alarmed or resentful if forewarnings have prepared them for unpleasant episodes that might otherwise have been considered the result of negligence or thoughtlessness

Control of Body Temperature Since fever ordinarily does little harm and imposes no great discomfort antipyretic drugs are rarely necessary and may obscure the effect of a specific therapeutic agent and of the natural course of the disease There are situations however in which lowering of the body temperature is of vital importance heat stroke postoperative hyperthermia delirium due to high pyrexia shock associated with fever Under these circumstances sponging the body surface with alcohol or the application of cool compresses to the skin and forehead may be employed When high internal temperature is combined with cutaneous vasoconstriction as in heat stroke or postoperative hyperthermia the cooling measures should be combined with massage of the skin in order to bring blood to the surface where it may be cooled Immediate immersion in a tub of ice water should be considered a lifesaving emergency procedure in patients with heat stroke if the internal body temperature is in excess of 108 F

If antipyretic drugs such as aspirin (0 3 to 0 6 Gm) are employed to bring about a fall in temperature the ill effects of the unpleasant diaphoresis sometimes associated with an alarming fall in blood pressure and the subsequent return of fever occasionally accompanied by a chill can be mitigated by enforcing a liberal fluid intake and by administering the drug regularly at 3 or 4-hr intervals

Rest and Activity In general the position that the patient takes in bed and the strictness with which bed rest is enforced will depend on what is most comfortable for the patient Barring those disorders such as acute febrile illnesses shock and other conditions discussed in context where recumbent bed rest is obligatory it is advisable to permit activity outside the bed as soon as the patient s strength permits Permitting the patient to use a bedside commode or to walk to a nearby toilet will usually involve less expenditure of energy than will the often futile struggle on a bedpan Unnecessary insistence on prolonged bed rest favors the development of venous thromboses in the lower extremities with the risk of pulmonary embolism decalcification of bone with the hazard of nephrolithiasis development of decubitus ulcers loss of strength and the greater likelihood of postural hypotension hypostatic pneumonia to say nothing of the corrosive effect on the patient s morale These risks are greater in the elderly patient As his weakness increases as the result of inactivity and his desire to bestir himself consequently diminishes it may require firm persuasion to convince him that increasing physical activity is essential

Bladder Function Patients confined to bed often have difficulty of urination and may even develop retention because of a variety of factors inability to void in the horizontal position excessive use of sedatives and narcotics adrenergic drugs such as ephedrine and antihistamines overdistention and

of abdominal distention due to aerophagia have been described in Chap 5 When this condition is present the most urgent decision is whether it requires surgical intervention If it is decided that the cause does not require immediate surgical correction measures should be instituted at once to correct contributing factors such as the hypoxia of pneumonia or fluid and electrolyte imbalances from a variety of causes especially potassium and sodium deficits or intracellular fluid excess Nasogastric intubation with a No 18F Levin tube and decompressive suction should be started at once Machine suction of the Gomco type is now generally preferred Regular irrigation of the tube preferably with bicarbonate solution is necessary to dissolve mucous plugs Plastic tubes are better tolerated than rubber tubes if prolonged intubation is required the tube should be changed about once a week Patients undergoing gastric suction may lose enormous quantities of gastric juice containing chloride potassium sodium and water requiring parenteral replacement Thirst is frequently present and there is a great temptation to permit the ingestion of fluids by mouth but this is a grievous mistake for ingested water leads to further loss of electrolytes as it is returned by suction Once fluid and electrolyte balance has been achieved thirst is rarely a problem

The greatest usefulness of the long double lumen tube or Miller Abbott tube is for preoperative decompression of the gastrointestinal tract of the patient with mechanical ileus a problem of surgery rather than of internal medicine In the event a Miller Abbott tube is selected and passed into a patient with paralytic ileus it is frequently necessary to pass a short Levin tube through the opposite nostril to maintain gastric decompression as the long tube descends into the small bowel However the long tube is not usually applicable for the patient with paralytic ileus because it does not pass when peristalsis is absent and is not needed if peristalsis has returned

It is rarely necessary for nasogastric decompression to be continued for more than 3 to 5 days Indeed *failure to relieve distention within 12 to 18 hr should call for a complete review of the problem and consideration of a surgical approach to it*

There are numerous tube designs to meet special purposes Alimentation by tubes is often necessary the route may be gastric or jejunal Jejunal alimentation is possible through extremely small plastic tubes No 6 to No 10F with the advantage of lessened nasal discomfort and irritation Small tubes of this sort may often be passed through esophageal or pyloric strictures and remain patent and well tolerated for weeks or months

A supplementary procedure of some usefulness in the treatment of established and severe distention is the administration of oxygen by the BLB mask The principle underlying this procedure is the removal of the predominantly nitrogen fraction of intestinal air Nitrogen transport in the blood is limited by solubility Hence elimination of nitrogen during inhalation increases the opportunity for nitrogen absorption from the bowel

Smooth muscle stimulants such as Pituitrin and Prostigmine are not recommended The former is potentially dangerous and the latter unnecessary when intubation and fluid management have been carried out intelligently Enemas serve no useful purpose

268 NUTRITION
Harold Brown

In the well nourished individual with an illness of short duration the problem of nutrition during illness is of minor importance one can usually follow the vagaries of the patient s appetite On the other hand in the patient debilitated by a long or severe bout of illness the physician is faced with the problem not only of maintaining his patient s state of nutrition but also of bringing about a return to the normal nutritional state The problem may be complicated by the patient s inability to take food by mouth because of anorexia weakness mechanical disturbances in the gastrointestinal tract or the state of consciousness

On occasion the depletion has been caused by the socioeconomic state of the individual food fads addiction to drugs or alcohol or psychiatric disturbances

Nutritional Requirements The nutritional requirements must be thought of in terms of calories proteins minerals and vitamins Fluids and Electrolytes are discussed in Chaps 48 and 49 and Gain and Loss of Weight Chap 21

The caloric requirements of the patient are derived from the basal metabolic requirement plus 30 per cent for bed activity and 8 per cent for each degree Fahrenheit of fever The basal caloric requirement is proportional to the individual s surface area which can be estimated from the height weight nomogram of DuBois (see Fig 206) For this calculation the "ideal weight or what the patient should weigh should be used The average surface area for adults is 1 6 sq m for women and 1 8 sq m for men The heat production per square meter of body surface diminishes progressively with age being 50 cal per hr at the age of ten to twelve years and about 32 cal per hr at the age of ninety years For the great majority of normal adults however the total basal heat production is

decompensation of the bladder due to the administration of large quantities of fluid The brisk diuresis following a mercurial injection may cause acute urinary retention in a person with mild subclinical prostatic obstruction

If the patient is not too ill permitting him to stand in the upright position may be all that is necessary to start the flow of urine or an enema of hot soapsuds or glycerin and water or the administration of neostigmine (Prostigmine) 0 5 to 1 0 mg hypodermically may be effective Because of the risk of infection especially in diabetic patients catheterization should be employed only when unavoidable Often but one catheterization is required in which case sulfisoxazole (Gantrisin) 0 5 Gm four times daily should be given as a prophylactic therapy for 2 or 3 days When urinary retention persists one may be compelled to resort to an indwelling catheter though infection is certain to occur if it remains in the urethra 72 hr or more In this case the bladder should be irrigated several times a day with an aqueous solution of benzalkonium chloride (Zephiran) in a dilution of 1 20 000 Since it is impossible to clear the bladder of infection in the presence of an indwelling catheter antimicrobial therapy should be deferred until the catheter has been removed in order to minimize the risk of establishing a proteus or resistant staphylococcus as the predominant organism After a few days when bladder compensation has been restored and the catheter removed antimicrobial therapy should be instituted and continued until urinary examination indicates that all traces of infection have disappeared

When the bladder is paralyzed because of neurologic disease a system of tidal drainage or drainage through a suprapubic cystotomy may be preferable to a constant or intermittent drainage through an indwelling catheter Zephiran 1 20 000 is used as the irrigating fluid

Constipation This is a common problem in individuals who are forced to limit their diet and activities Inadequate fluid intake especially in hot weather is a frequent important contributing factor A helpful and harmless method of overcoming constipation is the administration of a wetting agent dioctyl sodium sulfosuccinate (Velmol Colace or Doxinate) 150 to 200 mg each day alone or in conjunction with a vegetable mucin (Metamucil) 1 tsp daily Occasionally supplementary doses of a mild laxative such as milk of magnesia cascara or phenolphthalein may be required Because of the risk of lipoid pneumonia mineral oil preparations are best avoided especially in elderly patients or those suffering from neurologic disorders that interfere with the swallowing mechanism Fecal impaction is likely to occur in older or paralyzed patients and in those to whom sedatives narcotics barium or aluminum gels are being given A rectal examination should be made if the patient complains of rectal pain and inability to expel a stool or even if he states that small amounts of stool are being passed Should an impaction be found manual removal preceded by repeated small oil instillations may be necessary

Diarrhea Diarrhea that occurs in the course of a transitory illness will usually respond to a low residue diet aluminum hydroxide gels and when needed 1 or 2 tsp paregoric after each bowel movement When the diarrhea is more severe powdered opium 0 06 Gm or morphine sulfate 0 015 Gm every 4 to 6 hr and replacement of fluid and electrolytes will be required

Nausea and Vomiting Any obviously remediable cause should be corrected at once Frequently however the cause is obscure or cannot be controlled immediately and palliative measures may be required When the symptoms are severe chlorpromazine (Thorazine) should be administered 25 to 50 mg intramuscularly with an equal quantity of 2 per cent procaine to reduce the pain caused by the drug Thereafter 25 to 50 mg chlorpromazine may be given orally or by rectal suppository about four times daily Since the use of chlorpromazine may be attended by a significant fall in blood pressure the patient should be instructed to remain in the recumbent posture for about an hour after it has been given parenterally Other side effects especially sedation may occur and appropriate warnings should be given Because of the risk of jaundice and agranulocytosis the drug should not be given indiscriminately and when the symptoms are not urgent other drugs may be tried even if they are somewhat less effective The best of these are prochloperazine (Compazine) 5 to 10 mg four times daily meclizine (Bonamine) 25 to 50 mg twice daily or promethazine (Phenergan) 12 5 to 25 mg two or three times a day Meclizine is particularly efficacious when the nausea is caused in part by increased vestibular sensitivity as when it follows the administration of opiates or is brought on by motion sickness

Gastric irritation which may have been an initiating factor or may have developed subsequent to the vomiting may be decreased or controlled by swallowing sips of warm water tea bouillon or bland antacid preparations (Gelusil Basaljel) Food other than the liquids mentioned above should be withheld for 24 to 48 hr in the more severe cases later small servings of a bland diet may be permitted In a small percentage of cases the prompt correction of fluid and electrolyte deficits may be essential

Abdominal Distention Air swallowing or aerophagia is responsible for practically all the gas in the gastrointestinal tract The harmful consequences

ing the day and continuous drip feedings during the sleeping hours

Gavage should be used only with extreme caution in patients with esophageal varices and in patients who have lost their gag reflexes The tube should be irrigated daily and may remain for as long as a week

Sometimes diarrhea is occasioned by the high caloric formula This may be controlled by cutting down the amount of fat or adding applesauce or commercial pectin

For gavage or oral feeding mixtures extremely high in protein and calories can be devised by using casein or one of the many dried milk powders along with the usual cream and egg milkshakes Some of the dried milk powders (Lonalac Lesofac) have been made extremely low in fat and/or sodium chloride without too much loss of their palatability A wide variety of formulas is available depending upon the particular purpose of the supplement Commercially prepared mixtures (Calorigen Sustagen) for oral supplements or gavage feeding are now available These mixtures are sterile and will not clog the small nasogastric tube They contain adequate concentrations of protein calories and electrolytes to meet the patient s nutritional needs For short periods of feeding simpler liquids such as plain milk or eggnogs may be administered In the home it is possible to homogenize a complete meal with a Waring Blendor and to feed this material through a tube This will ensure a well balanced diet and avoid the necessity of making up separate formulas

It is well to add vitamin supplements for the malnourished patient The usual practice is to give five to ten times the recommended daily allowance of the factors which seem grossly deficient and one to five times the required amount of the other factors since in most cases there are multiple deficiencies even though there may seem to be a lack of only one specific factor A more detailed discussion of the symptomatology and treatment of deficiency disease is found in Chaps 55 to 59

Parenteral Feeding The oral route for alimentation has the obvious advantage of allowing the patient to take in a well rounded diet in much larger quantities than the parenteral route The latter however is often needed to supplement the patient s nutrition As the sole means for administration of food the parenteral route is imperfect It is extremely difficult to supply an individual s complete protein and caloric needs in this way Parenteral nutrition should be thought of in several categories In the first category there is the patient whose oral intake will be interrupted for periods up to one week and who can withstand some tissue loss In this patient the failure to supply adequate calories will mean varying degrees of adipose tissue loss Studies of rations for life raft survivors have indicated that about 100 Gm of glucose per day will afford almost a maximum nitrogen sparing action In this type of patient not much is gained by giving more than 100 Gm of glucose per day plus the needed fluids and electrolytes Additional glucose or other sources of calories will only conserve the body s fat stores In this situation there is probably little need for supplying protein or amino acids in an attempt to maintain the nitrogen balance

In the patient who is more debilitated or who must be maintained with parenteral feedings for longer periods one should attempt to establish caloric and nitrogen balance For this purpose there are available solutions of glucose fructose invert sugar (glucose and fructose) ethyl alcohol and amino acids The sugars and amino acids supply approximately 4 calories per Gm while alcohol supplies 6 calories per Gm

Glucose cannot be used in much higher concentrations than 10 per cent solutions without incurring a high incidence of phlebitis after a few days of administration In situations where the fluid intake must be rigidly restricted as in acute renal failure 30 to 50 per cent glucose solutions can be administered through a small plastic catheter which has been passed into a larger vein It is doubtful whether fructose solutions are more readily assimilated than glucose solutions by patients whose glucose tolerance is decreased by severe illness or diabetes as has been claimed

Ethyl alcohol can be used in 5 or 6 per cent solutions In addition to the sizable caloric supplement the alcohol will provide the usual psychic effects which may be beneficial to the patient with pain The alcohol solutions are given with glucose and/or amino acids It is probably safe to give up to 200 ml of 95 per cent alcohol by slow intravenous infusion over a 24 hr period without producing intoxication Alcohol should not be administered to the unconscious patient

Amino acid solutions (5 per cent) are readily assimilated sources of tissue nitrogen Numerous excellent preparations are now available and are free of side reactions if given more slowly than 300 to 400 ml per hr

Satisfactory emulsions of fat for parenteral administration have not been prepared

The uses of plasma whole blood and serum albumin are discussed elsewhere (p 1760)

The patient who is being fed via the parenteral route should receive therapeutic doses of vitamins

The problem of parenteral feeding is considerably simplified by proper attention to details such as the use of sharp needles avoiding the use of markedly hypertonic solutions and using veins distant from the elbow so that the patient may move

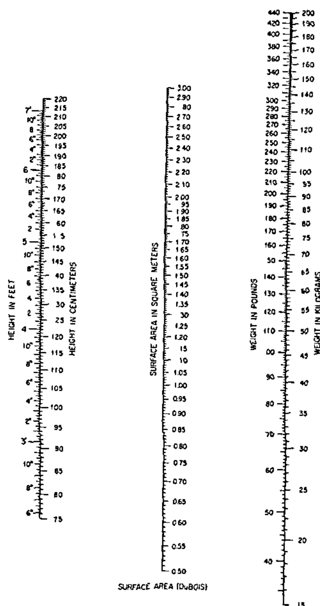

Fig 206 Nomogram for calculating surface area (*Du Bois Basal Metabolism in Health and Disease" Phila delphia Lea & Febiger*)

reasonably constant and ranges from 1400 to 1800 calories per day The average hospital diet will contain about 2000 calories

The recommended daily allowance for protein is set at 1 Gm/kg/day This is a generous allowance but in depleted states it may take three to five times as much to satisfy the protein needs Protein feeding in special situations such as acute renal failure nephrosis liver disease and other conditions is discussed in the appropriate chapters

The recommended daily allowances for vitamins in adult nutrition are tabulated in Chap 21 (p 184)

Vitamin K may be necessary in patients with impaired fat absorption Two to five mg per day of a water soluble preparation subcutaneously will make up the deficit Vitamin B_1 and folic acid should not be used without specific indications lest an underlying megaloblastic anemia be masked

Oral Feeding The sick patient all too frequently cannot take the full diet by mouth and one is faced with the problem of devising a diet which will suit the needs of the patient and yet be palatable to him

The dietitian can be of invaluable assistance in this situation Sometimes by more frequent smaller feedings plus supplements after the regular meal hours the patient s intake can be increased considerably The supplementary feedings can add many calories by utilizing nonsweetening carbohydrate such as lactose and by using additional fat in the form of cream and eggs or an oral fat emulsion (Lipomul Oral Ediol) Such a special diet should provide soft or liquid low residue meals which will reduce the need for mastication and limit the total bulk At times the caloric intake may be considerably increased by substituting high caloric vegetables such as peas and rice for those of negligible caloric content such as lettuce and cucumbers Eggnogs frappes and custards are frequently appealing and valuable supplements for a patient with a marginal oral intake

Both the physician and the dietitian must exercise considerable ingenuity in getting the patient to eat the prescribed foods An effort should be made to give the patient foods he will like and to serve them in an appealing fashion Unpleasant procedures or visits should not be scheduled at such a time that the patient will be emotionally upset during the meal period The size of the portions should be in accord with what the patient can consume so that he will not become discouraged at his inability to finish his meals For some individuals the use of wines or other alcoholic beverages for their stomachic qualities is beneficial

Gavage For the extremely weak anorectic or uncooperative patient tube feeding may be used with a small (2 to 3 mm) soft rubber or better still polyethylene or polyvinyl catheter There is little irritation from the nasogastric tube The liquid formula can be injected at intervals or as a continuous drip The former method is to be preferred for the attendant or nurse can aspirate any gastric residue before injecting 100 to 200 ml every 1 to 2 hr thus preventing gastric dilatation This technique also allows the diet to be kept in the refrigerator and avoids the possibility of bacterial contamination which is a distinct hazard with protein rich solutions On the other hand the constant drip procedure requires minimal nursing care and allows for alimentation over the entire 24 hr Simple devices can be arranged to keep the formula reservoir chilled Intermittent gavage can be used dur

should be crushed to ensure proper absorption or sodium barbital should be substituted Chloral hydrate (1 0 Gm) given with fruit juice at bedtime is also effective and may be substituted for the barbital if desired

Patients with serious mental agitation delirium or excitement who require prompt easily controlled relatively safe sedation should receive paraldehyde 15 to 30 ml by mouth in iced fruit juice or the same dose by rectum but diluted with 200 ml physiologic saline solution or 120 ml olive oil Generally it is wise to avoid the use of the barbiturates in highly agitated patients since occasionally they may precipitate serious mental confusion excitement or even manic tendencies Chloral hydrate 1 0 to 2 0 Gm by mouth or rectum is useful in the management of these individuals and frequently proves more satisfactory than the barbiturates

A word of caution about oversedation is wise in any discussion of sedative drugs All too frequently they are abused in that they are given when not needed the dose is too great or the wrong preparation is used They are a common source of constipation lead to fatigue and lack of energy and strength and interfere with the patient s recovery from his illness

When large doses of the quicker acting barbiturates 0 4 to 0 6 Gm daily are given for more than a week or two there is real danger of habituation which once it has developed is pernicious in character Withdrawal unless done skillfully and in graded steps may cause serious mental disturbance or precipitate convulsions The patient should not be encouraged to use sedative drugs as a crutch on which to limp through life One should search out and correct the underlying difficulty using sedation when necessary as a temporary helpful tool

PAIN

This sensory experience is unquestionably the most important signal of disease and serves a basic biologic principle that of preserving the life of the organism There are times however when it outlasts the disease to which it calls attention and giving rise to fear anxiety depression irritability and nervous exhaustion becomes detrimental unless relieved

Superficial pain arising in integumentary structures rarely presents a problem in therapy Acetylsalicylic acid 0 30 to 0 60 Gm orally every 4 hr usually suffices Acetophenetidin may be added These two drugs are a particularly effective combination when one element of pain is integumentary Commercial proprietary preparations of these drugs containing caffeine or amphetamine such as A S A Empirin compound or Edrisal are available in most pharmacies The caffeine or amphetamine is particularly useful if there is central nervous system depression When this type of pain is not effectively controlled by nonnarcotic analgesics codeine should be given Usually the addition of small amounts (8 to 30 mg) of codeine phosphate to the standard dose of acetylsalicylic acid and acetophenetidin is effective A preparation containing codeine phosphate 8 to 30 mg acetylsalicylic acid 0 23 Gm acetophenetidin 0 16 Gm and caffeine 0 032 Gm is commercially available (Empirin compound with codeine phosphate) Codeine 30 to 45 mg every 3 hr gives maximal analgesia with minimal side effects Adequate rest and relief of muscle tension should also be encouraged The application of heat, especially moist heat, is usually beneficial Occasionally cold applications are preferred but with the exception of cooling packs applied to an inflamed burning skin or to a causalgia cold is more likely to aggravate than to soothe the painful condition

Occasionally integumental and deep pains of skeletal structures are of such severity as to require more powerful narcotic analgesics such as meperidine hydrochloride (Demerol) in doses of 50 to 100 mg orally or intramuscularly methadone hydrochloride 5 to 10 mg orally or subcutaneously or dihydromorphine hydrochloride (Dilaudid) 1 0 to 2 0 mg orally or subcutaneously These drugs are most useful in conditions when sedation is not required When pain is unusually severe and some degree of euphoria is desired morphine is the ideal drug It should be given in doses of 8 0 to 15 0 mg orally or subcutaneously Frequently a dose as small as 4 0 to 6 0 mg will relieve pain without causing undesirable nausea and vomiting If the original dose is too small a second dose of the same or slightly larger size can be given in 2 hr This divided dose is less likely to induce nausea and vomiting than the larger single dose because the stimulating effect of the first dose is insufficient to produce these symptoms and the depressant effect which follows reduces the sensitivity of the vomiting mechanism or renders it refractory to the second dose Since all these narcotic analgesics are for the most part detoxified by the liver they either should not be used or should be given in only half the usual dose in cases of liver disease myxedema adrenal insufficiency and other states in which the metabolic rate is reduced Morphine and related narcotic analgesics tend to cause pruritus and therefore should be used with care in patients with skin irritability The possibility of initiating addiction in susceptible individuals must be carefully evaluated in every instance

If the patient exhibits mental tension insomnia and restlessness a sedative drug such as pheno-

his arm about Ordinarily an infusion of 1 to 2 liters is given over a period of 3 to 6 hr and when additional infusions are needed the needle is inserted in another vein Flexible polyethylene tubing which may be inserted through special thin walled needles seems to lessen the tendency to thrombophlebitis when solutions are administered over prolonged periods The tubing may be kept in the vein for several days On the rare occasions when it is necessary to give markedly hypertonic solutions the polyethylene tubing may be threaded into a larger vein such as the vena cava In this location the hypertonic solutions are rapidly diluted by the large volume of blood flowing by so that phlebitis is avoided

Hypodermoclyses are little used in adult practice because hypertonic solutions are not readily absorbed Furthermore since the solutions must first equilibrate with the extracellular fluid this type of administration is not so pleasant for the patient as intravenous therapy

Parenteral feeding should be maintained only as long as is absolutely necessary Usually the patient s own appetite is an excellent guide but one should avoid the possibility of producing nausea and vomiting by too enthusiastic resumption of oral intake after a long abstinence It is well to begin with easily digested liquids and soft solids in small feedings which can be taken as tolerated before going on to the regular diet As the oral intake increases the parenteral feeding can be cut down

Adjuvants Testosterone propionate 25 mg every other day and related androgens are sometimes useful for increasing the positive nitrogen balance in the sick Corticotropin and adrenocorticosteroids have a nonspecific appetite stimulating effect which has been of value in some situations where impaired appetite is a major problem as in hepatitis Regular insulin in 5 to 10 unit doses 20 min before meals has also been used to stimulate the appetite

269 SEDATION AND RELIEF OF PAIN

SEDATION

As a consequence of many disease states patients frequently develop nervous tension anxiety irritability restlessness or insomnia In the young nervous tense restless individual the mildly sedative action of 15 to 30 mg phenobarbital given after meals and at bedtime for 3 to at most 14 days will do much to bring about relaxation while more definitive measures are being initiated If apathy or weakness occurs the drug should be stopped or the dose reduced one half Bromisovalum (Bromural) 0 3 Gm after meals may be tried if phenobarbital is unsatisfactory Older patients in this category requiring mild sedation seem to do better on small doses of chloral hydrate 0 25 Gm after meals and at bedtime Chloral hydrate should not be given to patients with any degree of gastric distress because of its irritant properties but with this exception it may be used with good results in almost any situation

In general there are three varieties of wakefulness For best management treatment should be based on the type exhibited by the patient In younger patients the most frequently observed type of insomnia is the inability to fall asleep These individuals have developed more and more tenseness during the day and are unable to relax This type of insomnia usually lasts from 1 to 3 hr and then the individual sinks into an exhausted deep sleep which continues through the night For these patients a quickly acting fairly rapidly destroyed hypnotic such as secobarbital (Seconal)—0 1 Gm given 15 to 20 min before going to bed—is desirable

The second group consists of patients who are able to go to sleep but who awaken in 1 or 2 hr and lose sleep in the middle of the night Some are alternately awake and asleep all night Often these are sick individuals with a debilitating or painful illness who develop more pain and restlessness as muscles relax leaving painful areas unsplinted In others fever sweats dyspnea or other distressful symptoms develop and demand attention Frequently these patients secure good relief from 0 1 Gm pentobarbital (Nembutal) given at bedtime In cardiac patients who have Cheyne Stokes respiration or moderate orthopnea a rectal suppository of aminophylline 0 5 Gm given at bedtime will frequently relieve the respiratory distress and promote sleep When pain is a factor in insomnia acetylsalicylic acid (0 3 to 0 6 Gm) should be given with the sedative Occasionally codeine phosphate (30 mg) may be required when pain is severe

The third group of insomnia patients consists of those who go to sleep promptly and sleep well most of the night only to awaken too early in the morning Most of these individuals are older people who turn night into day They go to bed and get up earlier and earlier so that soon they are sleeping during the day and are alert during the night Into this category also fall those individuals who are under great tension worry or anxiety or are overworked and exhausted These people sink into bed and sleep through sheer exhaustion but around 4 or 5 A M awake with their worries and are unable to get back to sleep Most of these patients are benefited by barbital (0 3 Gm) given with fruit juice or milk at bedtime For debilitated patients the compressed tablet of insoluble material

should be crushed to ensure proper absorption or sodium barbital should be substituted Chloral hydrate (*1 0 Gm*) given *with fruit juice at bedtime* is also effective and may be substituted for the barbital if desired

Patients with serious mental agitation delirium or excitement who *require prompt easily* controlled relatively safe sedation should receive paraldehyde 15 to 30 ml by *mouth in iced fruit* juice or the same dose by rectum but diluted with 200 ml physiologic saline solution or 120 ml olive oil Generally it is wise to avoid the use of the barbiturates in highly agitated patients since occasionally they may precipitate serious mental confusion excitement or even manic tendencies Chloral hydrate 1 0 to 2 0 Gm by mouth or rectum is useful in the management of these individuals and frequently proves more satisfactory than the barbiturates

A word of caution about oversedation is wise in any discussion of sedative drugs All too frequently they are abused in that they are given when not needed the dose is too great or the wrong preparation is used They are a common source of constipation lead to fatigue and lack of energy and strength and interfere with the patient s recovery from his illness

When large doses of the quicker acting barbiturates 0 4 to 0 6 Gm daily are given for more than a week or two there is real danger of habituation which once it has developed is pernicious in character Withdrawal unless done skillfully and in graded steps may cause serious mental disturbance or precipitate convulsions The patient should not be encouraged to use sedative drugs as a crutch on which to limp through life One should search out and correct the underlying difficulty using sedation when necessary as a temporary helpful tool

PAIN

This sensory experience is unquestionably the most important signal of disease and serves a basic biologic principle that of preserving the life of the organism There are times however when it outlasts the disease to which it calls attention and giving rise to fear anxiety depression irritability and nervous exhaustion becomes detrimental unless relieved

Superficial pain arising in integumentary structures rarely presents a problem in therapy Acetylsalicylic acid 0 30 to 0 60 Gm orally every 4 hr usually suffices Acetophenetidin may be added These two drugs are a particularly effective combination when one element of pain is integumentary Commercial proprietary preparations of these drugs containing caffeine or amphetamine such as A S A Empirin compound or Edrisal are available in most pharmacies The caffeine or amphetamine is particularly useful if there is central nervous system depression When this type of pain is not effectively *controlled by nonnarcotic analgesics* codeine should be given Usually the addition of small *amounts (8 to 30 mg) of codeine phosphate to the* standard dose of acetylsalicylic acid and acetophenetidin *is effective A preparation containing* codeine phosphate 8 to 30 mg acetylsalicylic acid *0 23 Gm acetophenetidin 0 16 Gm and caffeine* 0 032 Gm is commercially available (Empirin compound *with codeine phosphate) Codeine 30 to* 45 mg every 3 hr gives maximal analgesia with minimal side effects Adequate rest and relief of muscle tension should also be encouraged The application of heat especially moist heat is usually beneficial Occasionally cold applications are preferred but with the exception of cooling packs applied to an inflamed burning skin or to a causalgia cold is more likely to aggravate than to soothe the painful condition

Occasionally integumental and deep pains of skeletal structures are of such severity as to require more powerful narcotic analgesics such as meperidine hydrochloride (Demerol) in doses of 50 to 100 mg orally or intramuscularly methadone hydrochloride 5 to 10 mg orally or subcutaneously or dihydromorphine hydrochloride (Dilaudid) 1 0 to 2 0 mg orally or subcutaneously These drugs are most useful in conditions when sedation is not required When pain is unusually severe and some degree of euphoria is desired morphine is the ideal drug It should be given in doses of 8 0 to 15 0 mg orally or subcutaneously Frequently a dose as small as 4 0 to 6 0 mg will relieve pain without causing undesirable nausea and vomiting If the original dose is too small a second dose of the same or slightly larger size can be given in 2 hr This divided dose is less likely to induce nausea and vomiting than the larger single dose because the stimulating effect of the first dose is insufficient to produce these symptoms and the depressant effect which follows reduces the sensitivity of the vomiting mechanism or renders it refractory to the second dose Since all these narcotic analgesics are for the most part detoxified by the liver they either should not be used or should be given in only half the usual dose in cases of liver disease myxedema adrenal insufficiency and other states in which the metabolic rate is reduced Morphine and related narcotic analgesics tend to cause pruritus and therefore should be used with care in patients with skin irritability The possibility of initiating addiction in susceptible individuals must be carefully evaluated in every instance

If the patient exhibits mental tension insomnia and restlessness a sedative drug such as pheno

barbital or sodium barbital may be given with the analgesic agents Sedative medication especially the quick acting barbiturates should not be used alone for the control of pain because they sometimes cause excitement and confusion under these circumstances

Visceral pain originating in the stomach gall bladder intestines or heart is usually very poorly controlled by the nonnarcotic analgesics Various combinations of acetylsalicylic acid and acetophenetidin usually prove to be ineffective unless given with sedatives The narcotic analgesics are the agents of choice but of course should never be given until the physician is certain that the relief of the pain will not mask the state of his patient If sedation is not desirable and if constipation is a troublesome problem the newer synthetic analgesics meperidine (Demerol) in doses of 50 to 100 mg orally or intramuscularly or methadone 5 to 10 mg by mouth or subcutaneously every 4 to 6 hr are recommended Like morphine these drugs are habit forming but they do not share with morphine the properties of strong analgesia sedation and euphoria Patients with severe visceral pain who are also *anxious or fearful and unable to* relax or sleep should be given morphine sulfate in doses of 8 to 15 mg subcutaneously The well known spasmogenic effects of morphine are partially counteracted by atropine sulfate 0 3 to 0 4 mg Aminophylline 0 5 Gm intravenously overcomes much of this undesirable spastic action a rectal suppository of 0 5 Gm although less effective may be substituted

Intractable pain due to incurable diseases such as metastatic carcinoma is one of the most difficult of therapeutic problems As a rule one resorts to narcotic drugs because of their strong analgesic action and habituation is accepted as the lesser of two evils An alternative is pain relieving surgery Section of peripheral nerves the lateral spinothalamic tracts in the spinal cord (cordotomy) or the lateral part of the medulla and lobotomy are relatively safe procedures which have advantages in certain cases over the continuous use of opiates

Section 2 Some Special Problems

270 BLOOD TRANSFUSIONS

Uses of Blood Transfusion By far the most important and most frequent uses of *whole blood transfusion* are to restore blood volume after hemorrhage trauma or burns and to maintain the concentration of circulating hemoglobin at an adequate level *in those types of anemia which cannot be re*lieved by specific measures such as liver or iron therapy

The extent to which blood may be lost when hemorrhage occurs within a viscus or a muscle mass *is frequently underestimated* Likewise it is not easy to judge the degree to which plasma has been depleted by leakage or how many red cells have been lost by hemolysis after a severe burn Severe arterial hypotension following a traumatic injury or an event suggesting the possibility of a concealed hemorrhage in the absence of evidence of other causes is indicative of a blood volume deficit exceeding 30 per cent i e 1 500 ml or more When the blood volume deficit is 20 per cent or less *patients are* unlikely to exhibit marked hypotension as long as they remain in the horizontal position In general it may be said that it is more common to underestimate than to overestimate the amount of blood needed in the management of shock and to restore blood which has been lost

Blood Substitutes It should be emphasized that no substitute for whole blood has been found which is in any way comparable to the value of the red corpuscles and plasma However if whole blood is not available to restore blood volume substitutes must be employed in emergencies Of these blood plasma is the best and in the dry form can be *transported easily and kept ready at hand* but the danger of transmitting the virus of homologous serum hepatitis is so great that the use of pooled plasma cannot be recommended Next in order of effectiveness is serum albumin which has a physio*logic effect* closely approaching that of plasma However it is very expensive For this and other reasons much attention has been given to the development of plasma expanders substances of such physicochemical properties that they will overcome the disparity between the capacity of the circulatory system and the circulating blood volume that exists in shock Of these the gelatins possess the fewest disadvantages but dextran a biosynthetic polysaccharide has been found to be very effective and is being used more and more Polyvinylpyrrolidone (PVP) is a colloid produced by the chemical combination of formaldehyde and acetylene which has some merit It should be borne

in mind that the plasma expanders should be employed only for the immediate emergency rather than repeatedly

When shock is clearly not due to blood loss transfusions are often withheld on the ground that such treatment is futile and may be dangerous Nevertheless where doubt exists concerning the nature of the shock whether oligemic or nonoligemic the administration of whole blood plasma or packed cells is justified and is not likely to be harmful In nonoligemic shock pressor amines such as norepinephrine have been found useful but such agents have been effective as interim therapy even in oligemic shock until whole blood could be obtained The uses of these agents are discussed in Chap 271

In the management of anemia other than that due to the acute loss of blood blood transfusions are commonly used more generously than is necessary or desirable The discovery of such anemia calls for careful study to determine its cause as discussed fully elsewhere (Chap 212) rather than the blind administration of blood Thus there is no justification for blood transfusion in iron deficiency anemias or in the macrocytic anemias with megaloblastic bone marrow unless the anemia is extremely severe or unless surgical measures must be carried out at once The patient who has such anemia has become adjusted to it and the sudden change produced by transfusion is unnecessary A physiologic response can be achieved by oral iron therapy or vitamin B_{12} or folic acid administration according to the nature of the deficiency Again in anemia associated with infection or in the management of the anemia of leukemia Hodgkin s disease or other disorders the treatment of the underlying condition whenever possible is preferable to blood transfusion Even in the management of aplastic anemia or other forms of anemia for which no specific therapy is available it is better to give only enough transfusions to maintain the hemoglobin at a level consistent with reasonable activity rather than to attempt to maintain a normal level Thereby the risk which each transfusion presents is reduced and the accumulation of iron in the tissues is less Such patients are often maintained quite satisfactorily at hematocrit levels between 35 and 40 ml per 100 ml blood

Whole blood plasma or albumin can be used to restore the colloid osmotic pressure of plasma to physiologic levels in cases of hypoproteinemia Intravenous injections of salt poor human serum albumin are particularly valuable in certain patients with hepatic cirrhosis and ascites the nephrotic syndrome idiopathic hypoproteinemia and the edema of malnutrition

As a means for providing protein nutrients in patients restricted to parenteral feeding other than as a temporary measure intravenous injections of whole plasma or of serum albumin are impractical This is because of their colloid osmotic activity and the consequent expansion of the recipient s plasma volume Whole blood is even less valuable as a protein nutrient in spite of its high protein content This is not only because of the expansion of the patient s plasma volume thereby but also because the contribution of the protein in the red corpuscles to the protein metabolic pool must await the natural destruction of the red corpuscles

There is no sound basis for the use of transfusions in the management of the great majority of infections It is true that blood transfusions have been employed effectively for the transfer of specific immune antibodies from convalescent donors to susceptible contacts where measles mumps and yellow fever have been present in epidemic form and immune transfusions have been considered to be of value in treating certain infections notably herpes ophthalmia and scarlet fever However other methods are now available for the management of most of these conditions Of the blood derivatives it should be mentioned here that gamma globulin is an important agent in measles prophylaxis and in the prevention of infectious hepatitis

Whole blood transfusions plasma or plasma fractions also can provide specific clotting factors which may be lacking in certain patients such as antihemophilic globulin (fraction I) prothrombin factors V (Ac globulin) and VII (spca) and fibrinogen Fresh normal plasma is capable of restoring all clotting factors and is particularly necessary for supplying factor V and the antihemophilic factor Stored plasma can be depended on only for prothrombin factor VII the plasma thromboplastin component (PTC) and fibrinogen When equipment constructed entirely of plastic or coated material is used fresh blood transfusions may also serve temporarily for the successful transference of blood platelets from one person to another As a method of treating conditions where leukocytes are needed this procedure is as yet neither practical nor very successful

Finally the removal of blood possessing pathogenic properties and its replacement with normal blood (exchange transfusion) is a valuable procedure in special circumstances as for example in certain cases of hemolytic disease of the newborn (erythroblastosis fetalis)

Although additional therapeutic benefits have been ascribed to blood transfusions their value and therapeutic rationale remain unproved Their use to pep up a patient who is not anemic and whose blood volume is normal is certainly unwarranted

Risks Inherent in Blood Transfusion The risk inherent in blood transfusion is not inconsiderable In spite of the general knowledge of the danger of

Table 137 TRANSFUSION REACTIONS

Type	Cause	Incidence, %
Pyrogenic	Bacterial pyrogen	1 8–2 9
Urticarial	Sensitivity (?)	0 8–1 1
Serum sickness	Unknown	Rare
Hemolytic	Mismatching of blood	0 1–0
Isoimmunization	Repeated transfusions and pregnancy	Not rare
Circulatory overload	Injudicious augmentation of blood volume	Not rare
Infectious	Grossly contaminated blood	Rare
Transmission of disease	Homologous serum jaundice syphilis malaria	0 4–1 0 Rare
Air embolism	Entry of air into vein via tubing	Rare
Cold reaction	*Cold agglutinins (?)*	Not rare
Hypocalcemia	Exchange transfusions	Not rare
Hemorrhagic diathesis	Massive transfusions	Rare (?)
Fat embolism	Transfusion via bone marrow	Rare

a hemolytic transfusion reaction resulting from mismatching of the major blood group antigens A B and D (Rh) and notwithstanding the care taken to avoid such errors the incidence of hemolytic reactions to blood transfusions is substantial (Table 137) The mortality of hemolytic transfusion reactions is approximately 50 per cent Furthermore as discussed earlier (Chap 45) there is a good chance of immunizing a recipient to one or more of the blood group antigens not tested for in the routine preparation for transfusion It is noteworthy that the risk from sensitization is increased if a woman is transfused with blood from her husband or one of his relatives because of the possibility of her having been previously sensitized during pregnancy to a blood group substance foreign to her but inherent in the fetus There is also the risk of erythroblastosis fetalis in subsequent pregnancies if sensitization occurs as a result of the transfusion

In addition to hemolytic transfusion reactions febrile or pyrogenic anaphylactic and infectious reactions may occur Pyrogenic and urticarial reactions are usually mild and may be induced by small thrombi in the transfused blood soluble toxic substances in new rubber tubing improperly cleaned tubing or insufficiently sterilized solutions which may contain small amounts of bacterial pyrogen Of great seriousness are reactions due to the administration of blood heavily laden with dead or viable bacteria which have gained access to the blood by accident Serum hepatitis is another serious and not completely avoidable complication of blood transfusion There is also the possibility of transmission of malaria or of syphilis but this can usually be avoided by appropriate inquiry and examination of the donor

Before subjecting a patient to blood transfusion thought should be given to his cardiovascular status In all persons with impaired cardiac function the administration of whole blood or other osmotically active solutions must be made cautiously and slowly since an increase in venous pressure and pulmonary edema are easily produced Particular care should be used in regard to concentrated serum albumin because of its capacity to withdraw fluid from the tissues into the circulation Such patients furthermore should be propped in a sitting position during the transfusion The so called "speed reaction" is the result of circulatory overloading and its manifestations are those of right sided *heart failure* It is produced by overrapid infusion in relation to the cardiovascular reserve of the patient and can be prevented by slow administration of blood If the purpose of transfusion is to raise the concentration of circulating hemoglobin rather than to increase the total blood volume red cell suspensions are as effective as are whole blood transfusions and offer the advantage that the volume of injected material is relatively small When it is not convenient to prepare red cell suspensions 60 to 80 per cent of the plasma can be withdrawn from the blood after spontaneous or mechanical sedimentation of the red cells thereby reducing the volume of injected material as well as its salt content

Patients who have *received many* transfusions may develop cold agglutinins and may react with a chill if blood is given without being warmed Sometimes allowing the blood to stand at room temperature is adequate but in many instances it is necessary to have some of the transfusion tubing rest in a water bath maintained at body temperature thus allowing the blood to be warmed before it enters the patient's vein Another complication which may develop in those subjected to repeated transfusions is sensitivity to a heat labile constituent *of fresh normal* plasma In such patients only well washed red cells can be used in transfusion

Except in emergency it is always wise to give the first 50 ml of blood slowly and under the scrutiny of a doctor or nurse In addition it is well whenever possible to wait 30 min in order to determine whether a reaction will occur Fatal transfusion reactions have occurred only when more than 300 ml of blood has been given It is unwise to use blood for transfusion which has been brought to room temperature cooled and then rewarmed since the likelihood of an infectious reaction is thereby increased

Universal Donor While the use of group O blood (universal donor) for general transfusion purposes is undesirable in certain types of hospitals which use transfusion therapy almost exclusively on an *emergency basis the practice* is followed In such situations the two chief hazards should be kept in mind One is the danger of mistyping A_2 donors as group O an error which can be eliminated by

serum or back typing The second danger that of the group O person whose serum contains high titers of anti A and anti B or both is met in part by attempting to discover and screen out such donors and in part by adding A and B substances to the group O blood

271 TREATMENT OF SHOCK

In the management of a patient with shock two general groups of procedures are essential The first involves the attempt to treat the cause and depending on the situation may involve control of bleeding management of diabetic coma treatment of an overwhelming infection etc The second involves the treatment of the circulatory disorder *per se*

When a patient has suffered a known cause of shock e g hemorrhage excessive vomiting *diarrhea trauma etc* it is not difficult to be on the alert for early manifestations increasing heart rate *restlessness faintness in the upright position* In a person who is seen for the first time and when the history is obscure as in some patients with *severe infections it may* be difficult to determine whether or not incipient shock is present

The classic circulatory signs do not usually develop until the venous return and the cardiac output have already undergone serious reduction When the skin is cold and moist (clammy) it is not usually necessary to search for other signs However patients with diabetic coma or other dehydrated states may have dry skin despite peripheral circulatory failure One of the earlier manifestations of shock is likely to be a decline of the blood pressure when the patient changes from the recumbent to the sitting posture This sign is more significant in young than in elderly patients Another relatively early sign particularly valuable in the postoperative state is the presence of a low urine volume—less than 25 ml per hr—despite an adequate intake of water and in the absence of significant fluid loss by extrarenal channels

Once it is recognized that circulatory failure is present or imminent the next problem is the decision as to whether the heart or the periphery is at fault (Chap 14) The cardiac disorders most likely to be confused with peripheral failure are painless coronary occlusion and ectopic tachycardia These and other causes of sudden heart failure should be excluded before vigorous fluid therapy is initiated

General Measures Either the flat or the Trendelenburg position may be preferred Significant elevation of body temperature i e to levels of 102 F or higher should be combated by sponging fans or wet sheets Pain should be relieved by narcotics with the realization that absorption destruction and excretion of drugs are likely to be impaired Oxygen is probably of some value and may be administered as described on p 1773

Administration of Fluid The fluid employed should replace that which is lacking and may be whole blood plasma plasma volume expander or solutions of electrolytes (Chaps 48 49 and p 1776) Intravenous administration of electrolyte free solutions of glucose is also indicated in order to provide water for insensible loss and for urine volume The fluids of choice are blood when shock is due to hemorrhage plasma and saline when burns are responsible a combination of blood and plasma when there is trauma while the shock due to loss of extracellular fluid should be treated by the use of the appropriate protein free electrolyte containing fluid

When doubt exists as to the type of solution for administration it is well to start with blood and to change to plasma or other solutions if the hematocrit subsequently becomes abnormally high When shock is severe the administration of blood should be continued at the rate of about 1 liter per hour for 3 or 4 hr The transfusion is terminated when the signs of shock have disappeared and when a free flow of urine (40 ml or more per hour) has appeared The development of gallop rhythm tachypnea venous distention increase in venous pressure rales at the bases or labored breathing *usually contraindicate further intravenous therapy* If the shock state is still present despite these phenomena it will usually be wise to reduce the rate of the infusion to that needed for the administration of vasopressor drugs to add *Digitalis lanata* (1 2 to 2 0 mg Cedilanid intravenously in about 2 hr) to the infusion fluid to elevate the patient s head and to administer oxygen

As soon as the state of shock has been brought under control isotonic (6 per cent) glucose solution should be administered in order to compensate for insensible loss of water The amount needed for this purpose is usually about 1 liter each 24 hr Since the storage of glucose as glycogen involves the transfer of potassium to the intracellular compartment it is often wise to add potassium chloride (3 Gm per liter) to the infusion fluid However this should not be done if oliguria is present When shock is due to diabetic coma potassium salts are especially important because of the migration of potassium into the cells as insulin induced glycogenesis occurs

Vasopressor Drugs Vasopressor drugs are indicated in all types of severe shock and in the milder instances when shock is known to be the result of

primary vasodilatation e g shock following spinal anesthesia or injury to the spinal cord

Of the several vasopressor drugs norepinephrine is the most potent vasoconstrictor It should be given only by intravenous infusion the utmost care being taken to avoid infiltration of the subcutaneous tissues since necrosis and sloughing of the skin are likely to ensue [should extravasation occur 5 mg phentolamine (Regitine) diluted in 20 ml water and infiltrated throughout the involved tissues has been found to prevent necrosis] Five to fifteen milliliters of a 1 1 000 solution are added to 1 liter of infusion fluid which is administered initially at a rate of 20 to 40 drops per minute The rate of infusion is then varied so as to maintain the blood pressure at a level approaching the preshock level of the patient It should be remembered that a systolic pressure of 120 mm Hg may represent serious hypotension in an elderly person with previous hypertension

Other vasopressor drugs enumerated in their descending order of effectiveness may be used metaraminol (Aramine) mephentermine (Wyamine) methoxamine (Vasoxyl) and phenylephrine (Neo synephrine) They may be administered subcutaneously or intramuscularly in doses of 3 to 15 mg or more approximately every 15 min the exact dose and frequency of administration depending on the behavior of the blood pressure or they may be given by intravenous infusion in concentrations of 30 to 200 mg per liter

Intravenous pressor drugs should be employed only when a physician or nurse is constantly at the bedside watching the patient the blood pressure and the urine volume and altering the rate of infusion according to the response

272 MANAGEMENT OF THE COMATOSE, THE DELIRIOUS, AND THE DEMENTED PATIENT

The various states of disturbed mental function regardless of their cause are often fatal because they not only represent an advanced stage of many diseases but also add their own characteristic burden to the primary disease The main objective in therapy is of course to find the cause—according to the procedures already outlined—and to remove it It often happens however that the disease process is one for which there is no specific therapy or as in hypoxemia or hypoglycemia it may already have expended itself before the patient had access to medical care Again the problem may be infinitely more complex for the disturbance of cerebral function may not be attributable to a single cause but rather be due to several possible factors acting in unison no one of which could account for the total clinical picture In lieu of direct therapy supportive measures must be used and indeed it may be said that chances of surviving the original disease often depend in large measure on their effectiveness The main essentials in the symptomatic management of the delirious demented and comatose patient are presented in Chaps 33 and 36

Care of the Comatose Patient The physician must give attention to every vital function in the insensate patient The following is a brief outline of the more important procedures In order for them to be carried out successfully a well coordinated team of nurses under the constant guidance of a physician is needed

1 If the patient is in shock this demands precedence over all other abnormalities The treatment of shock is discussed in Chap 271

2 Shallow and irregular respirations and cyanosis require the establishment of a clear airway and oxygen The patient should be placed in a semiprone position so that secretions and vomitus do not enter the tracheobronchial tree Pharyngeal reflexes are usually suppressed and therefore an endotracheal tube can be inserted without difficulty Stagnant secretions should be removed with a suction apparatus as soon as they accumulate since they will lead to atelectasis and bronchopneumonia Oxygen can be administered by mask in a 100 per cent concentration for 6 to 12 hr alternating with 50 per cent concentration for 4 hr The depth of respiration can be increased by the use of 5 to 10 per cent CO_2 for periods of 3 to 5 min every hour Atropine should not be given edema of the lungs and fluid in the tracheobronchial passages are not glandular secretions Furthermore atropine thickens this fluid and also may disturb temperature regulation of the body Aminophylline is helpful in controlling Cheyne Stokes breathing Respiratory paralysis dictates the use of a tank type respirator or electrophrenic stimulator but in the authors experience neither has been effective in comatose states in which there is disorganization of respiratory centers

3 The temperature regulating mechanisms may be disturbed and extreme hypothermia or hyperthermia or an unrecognized poikilothermia may occur In hyperthermia removal of blankets and use of alcohol sponges and cooling solutions are indicated

4 The bladder should not be permitted to become distended If the patient does not void a retention catheter should be inserted If more than

500 ml of urine is found in the bladder decompression must be carried out slowly over a period of hours Urine excretion should be kept above 800 to 1 000 ml per day The patient should not be permitted to lie in a wet or soiled bed

5 Diseases of the central nervous system may upset the control of water glucose and salt The unconscious patient can no longer adjust his intake of food and fluids by hunger and thirst Salt losing and salt retaining syndromes have both been described with brain disease Water intoxication severe hypopotassemia or hyperpotassemia or hyponatremia may of themselves prove fatal The maintenance of water and electrolytes has been discussed in Chap 48 If coma is prolonged the insertion of a stomach tube will make the problem of feeding the patient and maintaining fluid and electrolyte balance much easier

6 One should attempt to forestall the development of bronchopneumonia by the prophylactic use of penicillin and streptomycin or some other broad spectrum antibiotic and should watch the legs each day for signs of phlebothrombosis

7 If the patient is capable of moving suitable restraints should be used to prevent a possible fall out of bed

8 Convulsions should be controlled by measures outlined in Chap 35

Care of the Delirious Patient There is an advantage to treating the delirious patient in a general hospital because he often suffers from a medical disease which can be dealt with more adequately there than in a psychiatric hospital Furthermore a delirium seldom lasts more than a few days and if the patient can be kept on a medical ward the social stigma which attaches to incarceration in a mental institution is avoided In the authors experience only a few delirious patients are so agitated and noisy as to annoy others if this does happen many general hospitals now have some facilities for isolating the mentally disturbed patient Delirium of this severity is rare in infectious diseases but is of course not infrequent in alcoholism (delirium tremens) drug intoxication and other medical diseases

The first objectives are to quiet the patient and protect him against injury A private nurse an attendant or a member of the family should be with the patient at all times if this can be arranged Depending on how active and confused the patient is various types of restraint must be employed If he is extremely active and vigorous a locked room screened windows that cannot be opened by the patient and a low bed or mattress on the floor should be arranged It is often better to let the patient walk about the room than to tie him into bed this may excite or frighten him so that he struggles to the point of complete exhaustion and collapse If he is less active the patient can usually be kept in bed by leather wrist restraints a restraining sheet or a net thrown over the bed Unless it is contraindicated by the primary disease the patient should be permitted to sit up or walk about the room part of the day

All drugs that could possibly be responsible for delirium—particularly opiates barbiturates bromides atropine hyoscine cortisone adrenocorticotropic hormone (ACTH) and salicylates in large doses—should be discontinued Paraldehyde and chloral hydrate are the only sedatives that can be trusted under these circumstances Paraldehyde which is preferred may be given orally or rectally in doses of 10 to 12 ml For oral administration mixing it with fruit juices makes it more palatable though alcoholic patients will take it in any form and seem to enjoy it One must be cautious in attempting to suppress the agitation completely To accomplish this may require the use of very large doses of drugs and vital functions may be dangerously impaired The purpose of sedation is to assure rest and sleep so that the patient does not exhaust himself Continuous warm baths or warm packs are also effective in quieting the delirious patient but very few general hospitals have proper facilities for this valuable method of treatment

A fluid intake and output chart should be kept and any fluid and electrolyte deficit should be corrected according to the methods outlined in Chap 48 The pulse and blood pressure should be recorded at intervals of 2 hr in anticipation of circulatory collapse which is sometimes the cause of death particularly in delirium tremens In the event of circulatory collapse transfusions of whole blood and vasopressor drugs may be lifesaving

Finally the physician should be aware of many small therapeutic measures which may allay fear and suspicion and reduce the tendency to hallucinations The room should be kept well lighted and if possible the patient should not be moved from one room to another Every procedure should be explained in detail even such simple ones as the taking of blood pressure or temperature The presence of a member of the family may be a means of enabling the patient to maintain contact with reality

It may be some consolation and also a source of professional satisfaction to remember that most delirious patients tend to recover if placed in good hygienic surroundings and competently nursed The family should be reassured on this point They must also understand that the abnormal behavior and irrational actions of the patient are not willful but rather are symptomatic of a brain disease

primary vasodilatation e g shock following spinal anesthesia or injury to the spinal cord

7 If the patient is capable of moving suitable restraints should be used to prevent a possible fall out of bed

8 Convulsions should be controlled by measures outlined in Chap 35

Care of the Delirious Patient There is an advantage to treating the delirious patient in a general hospital, because he often suffers from a medical disease which can be dealt with more adequately there than in a psychiatric hospital Furthermore a delirium seldom lasts more than a few days and if the patient can be kept on a medical ward the social stigma which attaches to incarceration in a mental institution is avoided In the authors experience only a few delirious patients are so agitated and noisy as to annoy others if this does happen many general hospitals now have some facilities for isolating the mentally disturbed patient Delirium of this severity is rare in infectious diseases but is of course not infrequent in alcoholism (delirium tremens) drug intoxication and other medical diseases

The first objectives are to quiet the patient and protect him against injury A private nurse an attendant or a member of the family should be with the patient at all times if this can be arranged Depending on how active and confused the patient is various types of restraint must be employed If he is extremely active and vigorous a locked room screened windows that cannot be opened by the patient and a low bed or mattress on the floor should be arranged It is often better to let the patient walk about the room than to tie him into bed this may excite or frighten him so that he struggles to the point of complete exhaustion and collapse If he is less active the patient can usually be kept in bed by leather wrist restraints a restraining sheet or a net thrown over the bed Unless it is contraindicated by the primary disease the patient should be permitted to sit up or walk about the room part of the day

All drugs that could possibly be responsible for delirium—particularly opiates barbiturates, bromides atropine hyoscine cortisone adrenocorticotropic hormone (ACTH) and salicylates in large doses—should be discontinued Paraldehyde and chloral hydrate are the only sedatives that can be trusted under these circumstances Paraldehyde which is preferred may be given orally or rectally in doses of 10 to 12 ml For oral administration mixing it with fruit juices makes it more palatable though alcoholic patients will take it in any form and seem to enjoy it. One must be cautious in attempting to suppress the agitation completely To accomplish this may require the use of very large doses of drugs and vital functions may be dangerously impaired The purpose of sedation is to assure rest and sleep so that the patient does not exhaust himself Continuous warm baths or warm packs are also effective in quieting the delirious patient but very few general hospitals have proper facilities for this valuable method of treatment

A fluid intake and output chart should be kept and any fluid and electrolyte deficit should be corrected according to the methods outlined in Chap 48 The pulse and blood pressure should be recorded at intervals of 2 hr in anticipation of circulatory collapse which is sometimes the cause of death particularly in delirium tremens In the event of circulatory collapse transfusions of whole blood and vasopressor drugs may be lifesaving

Finally the physician should be aware of many small therapeutic measures which may allay fear and suspicion and reduce the tendency to hallucinations The room should be kept well lighted and if possible the patient should not be moved from one room to another Every procedure should be explained in detail even such simple ones as the taking of blood pressure or temperature The presence of a member of the family may be a means of enabling the patient to maintain contact with reality

It may be some consolation and also a source of professional satisfaction to remember that most delirious patients tend to recover if placed in good hygienic surroundings and competently nursed The family should be reassured on this point They must also understand that the abnormal behavior and irrational actions of the patient are not willful but rather are symptomatic of a brain disease

Care of the Demented Patient Dementia is a clinical state of the most serious nature and usually it is worthwhile to admit the patient to a hospital for a period of observation The physician then has an opportunity to see the patient several times in a new and fairly constant hospital environment and certain special procedures such as x rays of the skull lumbar puncture analysis for blood bromides basal metabolic rate and electroencephalogram can be carried out at this time The management of the demented patient in the hospital may be relatively simple if he is quiet and cooperative If the disordered mental function is severe a nurse attendant or member of the family must stay with him at all times Provision must be made for adequate food and fluid intake and control of infection using the same measures outlined for the delirious patient

Once it is established that the patient has an untreatable dementing brain disease a responsible member of the family should be apprised of the medical facts The patient should be told that he has a nervous condition for which he is to be given rest and treatment Nothing is accomplished by telling him more The family should be given the prognosis if the diagnosis is sufficiently certain for this to be possible If the dementia is slight and circumstances are suitable the patient may remain at home continuing activities of which he is capable He should be spared responsibility and be guarded against injury which might result from imprudent action If he is still at work plans for occupational retirement should be carried out If the home situation is unsuitable or when in the more advanced stages of the disease mental and physical enfeeblement become pronounced institutional care should be advised Seizures should be treated symptomatically Nerve tonics vitamins and hormones are of no value in checking the course of the illness or in regenerating decayed tissue They may however offer moral support for the patient and the family

The treatment of the coma associated with recurrent convulsions is discussed on pp 334 to 336

273 RESPIRATORY DISTURBANCES

T R Harrison and Ben V Branscomb

COUGH

The treatment of cough is considered on p 1386 in the discussion of chronic bronchitis The management of episodes of acute respiratory insufficiency in patients with chronic pulmonary disease has likewise been previously considered (p 1392) Acute pulmonary edema is discussed on p 1307 The discussion to follow deals with the management of those respiratory disturbances which may occur in almost any gravely ill patient

Measures to Secure a Clear Airway The cough reflex is depressed in moribund individuals and in patients under the effect of opiates or general anesthesia Persons with myasthenia gravis or poliomyelitis or indeed any severe debilitating disease may not be able to cough effectively because of weak muscular action The problem of bronchial drainage then becomes a matter of greatest urgency—of life or death—since retained mucus and bacteria will cause atelectasis and pneumonia

Measures to facilitate bronchial drainage in weakened and debilitated patients include elevation of the lower part of the body frequent turning and clearing of the pharynx by mechanical suction through a soft rubber catheter In most patients it is even possible to pass the suction tip of the catheter into the larynx trachea and main bronchi—a relatively simple and sometimes supremely important procedure which every physician should learn to do In patients whose cough mechanism is likely to be ineffective for some days e g in poliomyelitis tetanus or after a cerebrovascular accident tracheotomy may be performed to permit frequent clearing of the upper bronchial tree by suction Tracheotomy reduces the dead space by about one fourth and thus makes breathing more efficient

Mechanical devices are being developed which can increase the effectiveness of cough in weakened individuals They make use of positive pressure distention of the air passages followed by rapid reduction of pressure and result in a forceful exhalation almost as effective as a normal cough

Mechanical Aids to Respiration One of the most difficult decisions involved in the management of patients with diseases which embarrass or threaten respiration is whether or not to use some type of respirator To be placed in an iron lung is terrifying and one hesitates to subject the patient to the experience unless he is certain that it is necessary in order to save life On the other hand delay in the use of the respirator until the patient has become dyspneic and cyanotic may result in atelectasis and pneumonia which cannot then be corrected by the use of the respirator The patient often does not know when he is in need of assistance in respiration Useful warnings of respiratory difficulty are breathlessness upon attempting to talk and inability to count to 15 at 1 sec intervals on a single breath The standard basal metabolic rate machine is a useful device for recording the volume of each respiration on quiet breathing and on maximal

effort A tidal volume of less than 300 ml and a vital capacity of less than 500 ml indicate impending respiratory failure

The tank type respirator is the most generally used and reliable method An alternative procedure is the use of positive pressure supplied through a tracheotomy or an endotracheal tube by anesthesia apparatus or any of several automatic intermittent positive pressure machines

OXYGEN THERAPY

Indications *Acute cyanosis* of recent origin resulting from arterial hypoxia constitutes the most urgent indication for oxygen Cyanosis due to abnormal blood pigment or to arterial hypoxia brought about by venoarterial shunts is not an indication The situation is more complex in patients with chronic arterial hypoxia of pulmonary origin this is discussed on p 1392

Oxygen is of great value in patients with acute pulmonary edema but is rarely of much benefit in patients with chronic congestive failure unless cyanosis is pronounced

There is some doubt as to whether oxygen should be used routinely in patients with shock or with myocardial infarction who display little or no cyanosis or dyspnea If the arterial blood is already normally saturated one cannot increase the oxygen content much by breathing oxygen

Contraindications Aside from the expense involved and the possible psychologic disadvantages the only important contraindication to oxygen is the presence of well marked respiratory acidosis with compensatory rise in bicarbonate (p 1392)

Technical Considerations Rarely is it important to administer oxygen in concentrations greater than 40 per cent This may be achieved by a flow rate of 8 to 10 liters a minute of *humidified* oxygen using a nasal catheter a mask or a tent as dictated by the circumstances The catheter should not be used in the nose or the trachea of patients who have been subjected to tracheotomy

HICCOUGH

The following simple measures may be tried holding the breath drinking a large glass of water building up carbon dioxide in the tissue by rebreathing into a paper bag or through 3 ft of garden hose or inhalation of 5 to 10 per cent carbon dioxide relief of abdominal distention pressure on the eyeballs irritating the nose to produce a sneeze inducing nausea or vomiting by tickling the throat and pressure over the carotid sinus or over the phrenic nerves If there is gastric irritability lavage of the stomach and relief of any distention followed by administration of aluminum hydroxide or magnesium trisilicate (Gelusil) 4 to 8 ml every 2 to 4 hr may be helpful Mucosal reflex activity may be suppressed by a 0 5 per cent solution of cocaine hydrochloride in water given in a dose of 4 ml in a glass of water every hour for four doses Nupercaine lozenges (Nuporals) containing 1 mg Nupercaine may be dissolved in the mouth Occasionally two or three inhalations from a broken ampul of amyl nitrite will quickly end an attack Amphetamine (Benzedrine) sulfate 5 to 10 mg two or three times a day also sometimes gives relief Should the hiccough persist atropine 0 4 mg three or four times a day should be given followed by heavy sedation with pentobarbital 0 2 to 0 4 Gm

If all the above measures fail the phrenic nerve to the leaf of the diaphragm involved (when that can be determined by fluoroscopy) should be blocked with 0 5 per cent procaine Temporary relief by this measure justifies resorting to phrenic nerve crush in exceptionally stubborn cases Patients with emphysema or severe pulmonary or cardiac disease are poor candidates for crushing unless facilities are readily available for intubation artificial respiration and oxygen therapy

Section 3 "Iatrogenic" Disorders

274 "IATROGENIC DISORDERS

This term refers to adverse effects induced by the physician in caring for his patients not only the direct injuries that may result from therapeutic and diagnostic measures but also the hurt that can be inflicted by words or actions The term generally carries with it the connotation of an untoward effect that could have been avoided by exercise of reasonable care and knowledge on the part of the physician

Every medical procedure whether diagnostic or therapeutic contains within it the potentiality of harm and it would be impossible to afford the

patient all the benefits of modern scientific medicine if every legitimate step in diagnosis and therapy were withheld because of the possible risks involved Legitimate" here implies that the physician has weighed the pros and cons for a procedure and has concluded on rational grounds that it is advisable or essential for the relief of discomfort or the cure or amelioration of disease An iatrogenic disorder in the sense that it is here considered is one that is deemed to have ensued when the deleterious effects of the physician s action exceed any advantages that could have reasonably been anticipated

Not only are there unavoidable risks in the use of many of the newer and more potent therapeutic agents even when employed with the utmost caution and intelligence but the task of the physician is multiplied because the rate at which these new agents are introduced is usually more rapid than the pace at which contraindications become clear and understood Even when the need for a drug is indisputable its harmful effects can hardly be viewed with complacence but they are all the more deplorable when a better understanding of the patient s illness and an appreciation of the dubious or negligible indications for the use of a drug or other procedure would have prevented the accident None of the antibiotics is free from disturbing and sometimes dangerous side effects A persistent diarrhea due to a proctitis caused by a broad spectrum antibiotic may be far more distressing than the trivial respiratory infection for which it is prescribed The use of cortisone in a patient with relatively mild arthritis may cause a serious gastric hemorrhage or perforation the activation of a latent tuberculosis or a fatal adrenal crisis if a relatively mild stress is imposed shortly after the withdrawal of the drug Death may occur following an operative procedure when cortisone has been given and then withdrawn just prior to operation It is known that in spite of tropic hormone administration (thyroid stimulating adrenal cortical stimulating or follicle stimulating hormone) several weeks are required before a hypofunctioning gland is restored to normal Fatal homologous serum jaundice may follow the needless transfusions of plasma or blood and serious depression of the bone marrow may result from a large variety of drugs It is difficult to condone these and other catastrophes when the advantages expected of the offending agents could hardly have been commensurate with the risks inherent in their use Too often a serious accident has followed the use of a therapeutic agent when the physician at a loss for a diagnosis or a logical program of management has simply decided upon an ill advised "therapeutic trial" These hazards are likely to increase as patients become more and more informed of the miracles of modern research widely heralded in newspapers radio and television and more likely to demand that new discoveries be made available to them

Ill effects have been known to ensue from the injudicious administration of excessive doses of vitamins Fortunately the widespread use of vitamin mixtures fortified with minerals and other substances in ludicrously microscopic quantities usually involves nothing more serious than a waste of money But estrogens cleverly advertised in even the most reputable medical journals to relieve almost every complaint occurring in a middle aged woman may cause uterine bleeding which aside from being serious in itself inevitably raises the question of possible malignancy and the necessity for a diagnostic curettage Thyroid extract often given without justification and in doses far exceeding the endogenous level of secretory activity of a normal person may precipitate ectopic rhythms or even congestive failure Increasing evidence to incriminate the role of radiation in causing cancer and leukemia should make us wary of blithely ordering x ray therapy for enlarged thymus bursitis annoying but harmless skin disorders and even for diagnostic procedures especially when repeated without sound reason

There is one long standing "iatrogenic" disorder that deserves particular mention habituation to opiates Too often the administration of an opiate to a susceptible patient may initiate a lifelong problem all the more tragic when the need for sedation and relief of pain might have been met successfully by other measures Added caution must be employed in the care of professional associates who have ready access to these drugs The same warning applies to the use of synthetic derivatives of morphine or related substances which are sometimes glibly quoted as being relatively free from the danger of habituation

It is equally important to consider the harm which physicians may do to patients through ill considered or unjustified remarks No matter what the constitutional make up of the patient may be he approaches the physician with at least some degree of fear and concern His anxiety can be enhanced by a too serious demeanor a flippant remark or an impressive conference Particularly is it true that untoward remarks or actions have had ill effects in relation to heart disease Many persons have been crippled by cardiac neurosis because a physician has misinterpreted the significance of a heart murmur or an electrocardiographic finding Even when organic heart disease is present, the patient may be more severely disabled by an unjustified statement regarding prognosis or the imposition of too strict limitation of activity The physician s manner and behavior are important in

their implications to the patient A spirited bedside discussion regarding the interpretation of auscultatory findings may give the false impression that serious heart disease exists Conversely a solemn appearing conclave just out of earshot may cause the patient to conclude erroneously that his prognosis is grave or hopeless Sometimes the patient's pride is unwittingly offended because of his misinterpretation of terms overheard such as "degenerative process" or "neurosis" Similar sounding medical words have been confused e g a patient heard the word "leukopenia" and concluded that he had leukemia

The good physician appreciates the fact that he is always in a position where he may cause injury by his treatment by his words and by his behavior Skill in handling of patients cannot be taught all that one can do is to emphasize the importance of tact caution judgment and wisdom—ideals to be striven for but never fully attained Better than words are the examples of thoughtfulness and understanding that are exhibited by the medical teacher or senior staff physician in his ward or clinic conferences with students and younger colleagues But even if it were possible to finally achieve the goal—a generation of flawless physicians with infallible judgment and infinite wisdom—there would still be the patients who have uncanny capacity for misinterpreting the most innocent remarks and the most cautiously expressed opinions In the end "iatrogenic" illness is largely a matter of incomplete knowledge and fallacious judgment on the part of the physician conjoined with the fears and anxieties of the patient So long as medicine remains an art "iatrogenic" illness will remain The best hope for diminishing its incidence will come from a ceaseless consideration by the physician of the wisdom of each of his decisions and acts and from a greater appreciation of the mood and attitude of the person who consults the physician

patient all the benefits of modern scientific medicine if every legitimate step in diagnosis and therapy were withheld because of the possible risks involved Legitimate here implies that the physician has weighed the pros and cons for a procedure and has concluded on rational grounds that it is advisable or essential for the relief of discomfort or the cure or amelioration of disease An iatrogenic disorder in the sense that it is here considered is one that is deemed to have ensued when the deleterious effects of the physician s action exceed any advantages that could have reasonably been anticipated

Not only are there unavoidable risks in the use of many of the newer and more potent therapeutic agents even when employed with the utmost caution and intelligence but the task of the physician is multiplied because the rate at which these new agents are introduced is usually more rapid than the pace at which contraindications become clear and understood Even when the need for a drug is indisputable its harmful effects can hardly be viewed with complacence but they are all the more deplorable when a better understanding of the patient s illness and an appreciation of the dubious or negligible indications for the use of a drug or other procedure would have prevented the accident None of the antibiotics is free from disturbing and sometimes dangerous side effects A persistent diarrhea due to a proctitis caused by a broad spectrum antibiotic may be far more distressing than the trivial respiratory infection for which it is prescribed The use of cortisone in a patient with relatively mild arthritis may cause a serious gastric hemorrhage or perforation the activation of a latent tuberculosis or a fatal adrenal crisis if a relatively mild stress is imposed shortly after the withdrawal of the drug Death may occur following an operative procedure when cortisone has been given and then withdrawn just prior to operation It is known that in spite of tropic hormone administration (thyroid stimulating adrenal cortical stimulating or follicle stimulating hormone) several weeks are required before a hypofunctioning gland is restored to normal Fatal homologous serum jaundice may follow the needless transfusions of plasma or blood and serious depression of the bone marrow may result from a large variety of drugs It is difficult to condone these and other catastrophes when the advantages expected of the offending agents could hardly have been commensurate with the risks inherent in their use Too often a serious accident has followed the use of a therapeutic agent when the physician at a loss for a diagnosis or a logical program of management has simply decided upon an ill advised therapeutic trial These hazards are likely to increase as patients become more and more informed of the miracles of modern research widely heralded in newspapers radio and television and more likely to demand that new discoveries be made available to them

Ill effects have been known to ensue from the injudicious administration of excessive doses of vitamins Fortunately the widespread use of vitamin mixtures fortified with minerals and other substances in ludicrously microscopic quantities usually involves nothing more serious than a waste of money But estrogens cleverly advertised in even the most reputable medical journals to relieve almost every complaint occurring in a middle aged woman may cause uterine bleeding which aside from being serious in itself inevitably raises the question of possible malignancy and the necessity for a diagnostic curettage Thyroid extract often given without justification and in doses far exceeding the endogenous level of secretory activity of a normal person may precipitate ectopic rhythms or even congestive failure Increasing evidence to incriminate the role of radiation in causing cancer and leukemia should make us wary of blithely ordering x ray therapy for enlarged thymus bursitis annoying but harmless skin disorders and even for diagnostic procedures especially when repeated without sound reason

There is one long standing iatrogenic" disorder that deserves particular mention habituation to opiates Too often the administration of an opiate to a susceptible patient may initiate a lifelong problem all the more tragic when the need for sedation and relief of pain might have been met successfully by other measures Added caution must be employed in the care of professional associates who have ready access to these drugs The same warning applies to the use of synthetic derivatives of morphine or related substances which are sometimes glibly quoted as being relatively free from the danger of habituation

It is equally important to consider the harm which physicians may do to patients through ill considered or unjustified remarks No matter what the constitutional make up of the patient may be he approaches the physician with at least some degree of fear and concern His anxiety can be enhanced by a too serious demeanor a flippant remark or an impressive conference Particularly is it true that untoward remarks or actions have had ill effects in relation to heart disease Many persons have been crippled by cardiac neurosis because a physician has misinterpreted the significance of a heart murmur or an electrocardiographic finding Even when organic heart disease is present the patient may be more severely disabled by an unjustified statement regarding prognosis or the imposition of too strict limitation of activity The physician s manner and behavior are important in

APPENDIX
Laboratory Values of Clinical Importance

Laboratory Values of Clinical Importance

BODY FLUIDS AND OTHER MASS DATA

Body fluid total volume 50% (in obese) to 70% (lean) of body weight
Intracellular Approximately 67% of total
Extracellular 16–20% of body weight

Blood

Total volume Male 69 ml/kg body weight
Female 64 ml/kg body weight
Plasma volume Male 38 ml/kg body weight
Female 37 ml/kg body weight
Red cell volume Male 30 ml/kg body weight (1.15–1.21 L per sq m surface area)
Female 27 ml/kg body weight

$$\text{mEq (milliequivalent)} = \frac{\text{mg/100 ml} \times 10 \times \text{valence}}{\text{atomic weight}}$$

$$\text{mg/100 ml} = \frac{\text{mEq} \times \text{atomic weight}}{10 \times \text{valence}}$$

Atomic Weights of Elements Commonly Encountered in Clinical Medicine

Calcium	40.08	Magnesium	24.32
Carbon	12.01	Nitrogen	14.008
Chlorine	35.46	Oxygen	16.00
Copper	63.54	Phosphorus	30.98
Hydrogen	1.008	Potassium	39.100
Iodine	126.91	Sodium	22.997
Iron	55.85	Sulfur	32.07

CEREBROSPINAL FLUID

Cells <5 per cu mm all lymphocytes
Pressure initial (horizontal position) 0–180 mm water
Calcium 2.24–2.74 mEq/L 4.5–5.5 mg/100 ml
Chloride as Cl^- 120–130 mEq/L 430–460 mg/100 ml
Cholesterol 0.06–0.22 mg/100 ml
Colloidal gold test Not more than one in any tube
Creatinine 0.4–1.5 mg/100 ml
Glucose 50–75 mg/100 ml
Magnesium (average) 2.7 mEq/L 3.3 mg/100 ml
Nonprotein nitrogen 12–30 mg/100 ml
Protein 14–45 mg/100 ml
Potassium 3.5–5.0 mEq/L 13.7–20.0 mg/100 ml
Urea nitrogen 6–15 mg/100 ml

CHEMICAL CONSTITUENTS OF BLOOD

Albumin serum 4.0–5.2 Gm/100 ml
Ammonia, whole blood venous 30–70 μg/100 ml
Amylase whole blood (Somogyi) 60–180 units 100 ml
Ascorbic acid whole blood 0.4–1.0 mg/100 ml
Leukocytes 25–40 mg/100 ml
Base total serum 145–155 mEq/L
Bilirubin total serum (Malloy Evelyn) 0.1–0.8 mg/100 ml
Direct serum 0.1–0.2 mg/100 ml
Indirect serum 0.1–0.6 mg/100 ml
Calcium serum 4.5–6.0 mEq/L 9–11 mg/100 ml
Carbon dioxide–combining power serum 21–28 mEq/L 50–65 vol %
Carbon dioxide content serum 21–30 mEq/L 50–70 vol %
Carbon dioxide tension serum 38–40 mm Hg
Carotenoid serum 100–200 μg/100 ml
Chloride serum (as Cl) 98–106 mEq/L 350–375 mg/100 ml
Cholesterol Total serum (Man Peters method) (mean ± 1 SD) 194 ± 36 mg/100 ml
Esters serum 100–180 mg/100 ml
Cholesterol ester fraction of total cholesterol serum 68–72%
Copper serum (mean ± 1 SD) 114 ± 14 μg/100 ml
Corticoids plasma (Porter-Silber) (mean ± 1 SD) 13 ± 6 μg/100 ml
Creatinine serum (Peters) 1–1.5 mg/100 ml
Fat neutral serum 150–250 mg/100 ml
Fatty acids serum 380–465 mg/100 ml
Fibrinogen plasma 0.2–0.4 Gm/100 ml
Globulin serum 1.3–2.7 Gm/100 ml
Glucose (fasting) blood (Nelson-Somogyi) 60–90 mg/100 ml
Hemoglobin blood (sea level)
Males 14–18 Gm/100 ml
Females 12–16 Gm/100 ml
Icterus index, serum 4–6 units
Iodine protein bound serum 4–8 μg/100 ml
Iron serum males and females (mean ± 1 SD) 105 ± 37.8 μg/100 ml
Iron binding capacity serum (mean ± 1 SD) 339 ± 30.8 μg/100 ml
Ketones total 0.5–1.5 mg/100 ml
Lipase serum (Cherry Crandall) 1.5 ml N/20 NaOH (upper limit of normal)
Lipid phosphorus (Man Peters) (mean ± 1 SD) 9.2 ± 1.4 mg/100 ml
Lipids total serum 500–600 mg/100 ml
Magnesium serum 1.5–3.0 mEq/L 2–3 mg/100 ml
Methemoglobin <1.8 %
Nitrogen nonprotein serum 15–35 mg/100 ml
Oxygen capacity blood 18–22 vol %
Oxygen content Arterial blood 17–21 vol %
Venous blood arm 10–16 vol %
Oxygen per cent saturation (sea level)
Arterial blood 94–96 vol %
Venous blood arm 60–85 vol %
Oxygen tension serum 95–100 mm Hg
pH serum 7.37–7.45
Phosphatase acid total serum Bodansky method 0.2–0.8 unit/100 ml
Gutman or King Armstrong method 1–4 units/100 ml

Kidney

Clearances (corrected to 1.73 sq m body surface area)

Measures of glomerular filtration rate

Inulin clearance (C_I) Males 124 ± 25.8 ml/min

Females 119 ± 12.8 ml/min

Endogenous creatinine 91–130 ml/min

Urea 60–100 ml/min

Measures of effective renal plasma flow and tubular function

Para aminohippuric acid (C_{PAH})

Males 654 ± 163 ml/min

Females 594 ± 102 ml/min

Tubular maximum for *PAH* males and females 77.2 mg/min

Diodrast 600–800 ml/min

20–30% excretion in 15 min

Concentration and dilution test

Specific gravity of urine After 12 hr fluid restriction 1.025 or more

After 12 hr water intake 1.003 or less

Phenolsulfonphthalein After intramuscular injection

Excretion in urine in 15 min 25% or more

Excretion in urine in 2 hr 55–75%

After intravenous injection

Excretion in urine in 2 hr 55–75%

Specific gravity maximal 1.022–1.028

Tubular reabsorption phosphorus

79–94% of filtered load

Metabolic

Basal metabolic rate −10% to +10% of mean standard

Creatine tolerance 0% ingested creatine retained in adults

Glucose tolerance 100 Gm glucose or 1.75 Gm glucose/kg body weight p.o. Blood sugar not more than 160 mg/100 ml after 1 hr return to normal in 2 hr sugar not present in any urine specimen

Radioactive iodine (I^{131}) Uptake 20–50% of administered dose

Excretion 30–70% of administered dose in 24 hr following tracer dose provided renal function is normal

Protein bound serum or plasma <0.3% of administered dose/l plasma at 72 hr following tracer dose

Conversion ratio <3 % at 24 hr

Water test (Saffer) 80% excretion of a 1,500 ml water load in 4 hr

HEMATOLOGIC EXAMINATIONS

(See also Chemical Constituents of Blood)

Bone Marrow (See Table 13, p. ?)

Erythrocytes (See Table below)

NORMAL VALUES AT VARIOUS AGES

Age	Red cell count millions per cu mm	Hemoglobin Gm per 100 ml	Vol packed RBC ml per 100 ml	Corpuscular values			
				MCV cu μ	MCH γγ	MCHC %	MCD μ
First day	5.1 ± 1.0	19.5 ± 5.0	54.0 ± 10.0	106	38	36	8.6
2–3 days	5.1	19.0	53.5	105	37	35	
4–8 days	5.1	18.3 ± 4.0	52.5	103	36	35	
9–13 days	5.0	16.5	49.0	98	33	34	
14–60 days	4.7 ± 0.9	14.0 ± 3.3	42.0 ± 7.0	90	30	33	8.1
3–5 months	4.5 ± 0.7	12.2 ± 2.3	36.0	80	27	34	7.7
6–11 months	4.6	11.8	35.5 ± 5.0	77	26	33	7.4
1 year	4.5	11.2	35.0	8	25	32	7.3
2 years	4.6	11.5	35.5	77	25	32	
3 years	4.5	12.5	36.0	80	27	35	7.4
4 years	4.6 ± 0.6	12.6	37.0	80	27	34	
5 years	4.6	12.6	37.0	80	27	34	
6–10 years	4.7	12.9	37.5	80	2	34	7.4
11–15 years	4.8	13.4	39.0	82	28	34	
Adults							
Females	4.8 ± 0.6	14.0 ± 2.0	42.0 ± 5.0	87 ± 5	29 ± 2	34 ± 2	7.5 ± 0.3
Males	5.4 ± 0.8	16.0 ± 2.0	47.0 ± 7.0	87 ± 5	29 ± 2	34 ± 2	7.5 ± 0.3

MCV = mean corpuscular volume MCH = mean corpuscular hemoglobin MCHC = mean corpuscular hemoglobin concentration MCD = mean corpuscular diameter (Wintrobe *Clinical Hematology* 4th ed Philadelphia Lea & Febiger 195?)

Phosphatase acid tartrate sensitive (Fishman Lerner)
<0.6 unit/100 ml

Phosphatase alkaline serum Bodansky method
1–4 units/100 ml
King Armstrong method 8–13 units/100 ml

Phospholipids serum 150–250 mg/100 ml

Phosphorus inorganic serum 1–1.5 mEq/L
3–4.5 mg/100 ml

Potassium serum 3.5–5.0 mEq/L 13.7–20.0 mg/100 ml

Proteins total serum 6.5–8.0 Gm/100 ml

Proteins electrophoretic fractions (Tiselius)

	Plasma %	*Serum* %
Albumin	55.2	58 ± 3
Globulins α_1	5.3	5 ± 2
α_2	8.7	12 ± 3
β	13.4	11 ± 4
Fibrinogen	6.5	
Globulins γ_1 }	11.0	2 ± 2
γ_2		12 ± 3

Prothrombin plasma (Quick method)
11–12 sec (cf control)

Sodium serum 132–142 mEq/L
303–327 mg/100 ml (as sodium)
771–832 mg/100 ml (as sodium chloride)

Sulfates inorganic serum 0.5–1.5 mg/100 ml

Urea nitrogen whole blood 10–20 mg/100 ml

Uric acid serum enzymatic method (Praetorius) (mean ± 1 SD)
Males 5.0 ± 1.2 mg/100 ml
Females 3.8 ± 0.9 mg/100 ml

Uric acid serum (Talbot) 2.5–5.0 mg/100 ml

Vitamin A serum 50–100 μg/100 ml

FUNCTION TESTS

Liver

Bromsulphalein (5 mg/kg body weight IV)
5% or less retention at end of 45 min

Cephalin-cholesterol flocculation 0 or + at 48 hr

Galactose tolerance after ingestion of 40 Gm
Excretion of not more than 3 Gm in urine in 5 hr

Hippuric acid *After ingestion of 6 Gm sodium benzoate*
Excretion of 3–3.5 Gm hippuric acid in urine in 4 hr
After injection of 1.77 Gm sodium benzoate IV
Excretion of 0.70 Gm hippuric acid in urine in 1 hr

Prothrombin test Increase of 15% or more in prothrombin concentration in blood in 24 hr after injection of synthetic vitamin K

Serum glutamic oxalacetic transaminase (SGOT)
(mean ± 1 SD) 22 ± 7 units/ml/min

Serum glutamic pyruvic transaminase (mean ± 1 SD)
16 ± 9 units/ml/min

Thymol turbidity 3 units or less

Urobilinogen
Urine Semiquantitative (2 hr) 0.5–1.5 units
Quantitative 1–3.5 mg/24 hr
Stool Semiquantitative (per 100 Gm) <350 units
Quantitative 40–280 mg/24 hr

Zinc sulfate turbidity <4 units

Circulation

Cardiac output (Fick) 3.3 L/sq m/min

Circulation time Arm to lung ether 4–8 sec
Arm to tongue calcium gluconate 12–18 sec
Decholin 10–16 sec
Saccharin 9–16 sec

Pressures intracardiac and intraarterial
Aorta Systole 120 mm Hg
Diastole 80 mm Hg
Atrium Left (mean) 5 mm Hg
Right (mean) 2 mm Hg
Pulmonary artery Systole 25 mm Hg
Diastole 10 mm Hg
Wedge (mean) 9 mm Hg
Ventricle left Systole 120 mm Hg
Diastole 5 mm Hg
Ventricle right Systole 25 mm Hg
Diastole 0 mm Hg
Venous (antecubital) 70–140 mm H_2O

Gastrointestinal

Gastric juice basal Free acid
5–25 units (ml N/10 alkali per 100 ml gastric fluid)
Total acid 5–10 units higher than free acid
Volume (fasting) 5–150 ml
Chlorides (as Cl) (mean and range)
104 (24–127) mEq/L
HCl free 200 mg/100 ml
Reaction as pH 1.6–1.8
Volume 24 hr 2–3 L
Following standard meal Free acid 20–70 units
Total acid 10 units higher than free acid
Volume in 1 hr 50–100 ml
Following alcohol meal Maximum free acid [illegible]0 units
Maximum total acid 85 units

Jejunal secretion fasting Chloride 80–140 mEq/L
HCO_3 2–32 mEq/L
Total base 110–160 mEq/L

Pulmonary

Maximum breathing capacity L/min
Males
86.5 − (0.522 × age in yr) × body surface in sq m
Females
71.3 − (0.474 × age in yr) × body surface in sq m

Residual volume 1.0–1.5 L

Vital capacity (*VC*) total
Males
4–6 L (27.63 − (0.112 × age in yr) × ht cm)
Females
3–4.5 L (21.78 − (0.101 × age in yr) × ht cm)
Timed 1 sec 80% of total
3 sec 93% of total

Total capacity (supine) in ml $\frac{VC}{80} \times 100$ at 16–34 yr

$\frac{VC}{76.6} \times 100$ at 35–49 yr $\frac{VC}{69.2} \times 100$ at 50–69 yr

$\frac{\text{Residual volume}}{\text{total capacity}} \times 100$ 20.0 at 16–34 yr
23.4 at 35–49 yr 30.8 at 50–69 yr

Erythrocytes (continued)

Fragility, osmotic: Slight hemolysis 0.45–0.39%
  Complete hemolysis 0.33–0.30%
Hemochromogens in plasma: 3–5 mg/100 ml
 Life span: Normal survival 120 days
  Chromium half life (T ½) 28 days
Plasma iron turnover rate: 38 mg/24 hr (0.47 mg/kg)
Protoporphyrin, free erythrocyte (F.E.P.):
  20–38 μg/100 ml RBCs
Reticulocytes: 0.5–2.0% of red cells
Sedimentation rate: Westergren: <15 mm/1 hr
 Wintrobe: Male 0–9 mm/1 hr
  Female 0–20 mm/1 hr

Leukocytes

NORMAL VALUES

	Per cent	Average	Minimum	Maximum
Total number per cu mm		7,000	5,000	10,000
Neutrophils				
Juvenile	3–5	300	150	400
Segmented	54–62	4,000	3,000	5,800
Eosinophils	1–3	200	50	250
Basophils	0–0.75	25	15	50
Lymphocytes	25–33	2,100	1,500	3,000
Monocytes	3–7	375	285	500

Platelets and Coagulation

Platelets per cu mm: direct counting method
 200,000–300,000
Bleeding time (Ivy method): majority and range
 1–5 min, 0–12 min
Clot retraction time: Begins in 30 min, complete in less than 24 hr, usually <6 hr
Coagulation time (Lee-White method):
 majority and range: 5–15 min, 2–19 min

Schilling Test

Excretion in urine of orally administered radioactive vitamin B_{12} following flushing parenteral injection of B_{12}: 7–22%

STOOL

Bulk: 100–200 Gm daily
Dry matter: 23–32 Gm (4–38% of fresh feces)
Fat, on unregulated diet: Total 7–25% of dry matter
 Neutral: 2.5–12% of dry matter, 25–60% of total fat
Fatty acid: Free 1–10% of dry matter
 Combined as soap 0.5–12% of dry matter
Nitrogen excretion: <1.7 Gm/day
Protein content: Minimal
Urobilinogen: 40–280 mg/24 hr
Water: Approximately 65%
Coproporphyrin: 400–1,000 μg/24 hr

URINE

Acidity, titratable: 125–150 mEq/24 hr
α-Amino nitrogen: 0.4–1.0 Gm/24 hr
Ammonia: 30–50 mEq/24 hr
Amylase (Somogyi): 260–950 mg of glucose/24 hr
Calcium: 10 mEq or 200 mg calcium diet:
  <7.5 mEq/24 hr or <0.15 Gm/24 hr
Copper: 0–25 μg/24 hr
Coproporphyrins (types I and III): 100–300 μg/24 hr
Creatine, as creatinine: Adult males <50 mg/24 hr
 Adult females <100 mg/24 hr
Creatinine: 1.0–1.6 Gm/24 hr
Estrogens (Jailer method): Male 5–20 μg/24 hr
 Female (nonpregnant):
  15–100 μg/24 hr depending on time of menstrual cycle
Glucose, true (oxidase method): 50–300 mg/24 hr
Ketones, total (mean ± 1 SD): 50.5 ± 30.7 mg/24 hr
17-Ketosteroids (Holtorf-Koch method):
 Male 8–20 mg/24 hr
 Female 6–15 mg/24 hr
11-Oxysteroid, or corticoids (Porter-Silber method):
  2.2–8.0 mg/24 hr
Protein: <50 mg/24 hr
Urobilinogen: 1–3.5 mg/24 hr
